Juvenile scions on mature understocks were also tested. Forty-two grafts, potted on November 17, 1958, were kept in a glasshouse at 60° F. On June 1, 1959, none of the scions had produced any growth which was not fully juvenile. The influence of temperature has been noted in a few other plants. Hudson and Williams[3] noticed that high temperatures favoured the production of the juvenile leaf type on raspberry shoots, and Njoku[4] found a similar relationship in *Ipomoea*, as did Fisher[2] on *Ranunculus*.

Table 2. RESPONSES OF SHOOTS ON BUDDED AND GRAFTED PLANTS IN THREE ENVIRONMENTS

Treatment	80° F.		60° F.		Lath house	
	No. of plants	No. juvenile	No. of plants	No. juvenile	No. of plants	No. juvenile
Budded	73	71	96	14	77	1
Grafted	106	27	101	3	103	0

These experiments confirm the observations of Doorenbos, but also show that reversions to the juvenile form are influenced by temperature and also by the amount of mature tissue present in the graft combinations initially.

BACTERIOLOGY

Isolation of Lysozyme-soluble Mucopeptides from the Cells Wall of *Escherichia coli*

THE cell walls of the Gram-positive bacteria have been shown by Salton[1] and by Cummins and Harris[2] to consist mainly of polymers, later termed mucopeptides, containing a limited number of amino-acids (usually four), two amino-sugars and sometimes one or more hexoses. Two of the amino-acids, alanine and glutamic acid, are, at least partly, in the D-form. This, together with the occurrence of muramic acid, and sometimes of diaminopimelic acid as well, distinguishes mucopeptides from other types of macromolecule. A further characteristic is sensitivity to lysozyme. The mucopeptides from some bacterial species are completely digested by this enzyme, and all appear to be attacked slightly[3]. The synthesis of mucopeptide in washed suspensions is inhibited by penicillin[4,5].

The cell walls of the Gram-negative bacteria are much more complex (see Salton[6]) and contain a good deal of protein and polysaccharide. However, the presence of mucopeptides similar to those of the Gram-positive bacteria was indicated by the fact that Gram-negative cells could be lysed by treatment with lysozyme[7], and that penicillin produced osmotic fragility in *E. coli*[8]. In addition, when walls of *E. coli* were treated with lysozyme, soluble fragments were recovered containing the characteristic components of mucopeptide, namely, diaminopimelic acid, muramic acid, glucosamine, alanine and glutamic acid[9]. The object of the work to be described was to separate the mucopeptides of *E. coli* sufficiently from protein and polysaccharide to allow its composition and some of its properties to be examined. The procedure finally adopted was as follows.

The bacteria (about 10 gm. dry weight) were broken by shaking with Ballotini beads in a Mickle disintegrator, and the walls sedimented at 10,000*g*. The sediment was suspended in water and heated at 100° C. for 30 min. to destroy any lytic enzymes that might have been present. All further procedures were carried out at room temperature unless otherwise stated. The crude wall preparation was then extracted three times with ethanol/ether (3 : 1) and then with ether. The residue was dried in air, and treated for the reduction and alkylation of disulphide bonds[10] in the protein by suspending the powder in 10 *M* urea

* GM = glucosamine; **DAP = diaminopimelic acid.

† Mur. = muramic acid. Both hexosamines are N-acetylated in *S. aureus* and are presumably so in *E. coli*, although this has not been determined. The molar ratios for coliform mucopeptides were determined as previously described (ref. 13). The values for strains of micrococci are those quoted by Rogers and Perkins (ref. 11).

(50 ml.) containing mercaptoethanol (1 ml.). After several hours, excess iodoacetic acid was added, and the product washed well and digested overnight at 35° C. with pepsin (20 mgm.) in $N/20$ hydrochloric acid. The product still contained more than 50 per cent protein. To remove this, it was extracted three times with 90 per cent formic acid (20 ml.) and twice with 90 per cent phenol (20 ml.). Finally, the residue was extracted three times with 10 ml. of copper ethylenediamine (6 per cent copper hydroxide and 8 per cent ethylenediamine) and washed several times with $N/20$ hydrochloric acid to remove copper. Although some mucopeptide was always lost at this stage, the extraction removed mainly protein and polysaccharide.

After drying with acetone and ether, a white powder was obtained representing about 1 per cent of the bacterial mass, and containing the following major constituents: diaminopimelic acid, lysine, serine, glutamic acid, alanine, glucosamine and muramic acid. Together these accounted for 75–80 per cent of the total material. In addition, chromatography of acid hydrolysates revealed the presence of small amounts of all the other amino-acids characteristic of protein, and these together represented a further 10 per cent. The remainder of the preparation consisted of unidentified carbohydrate.

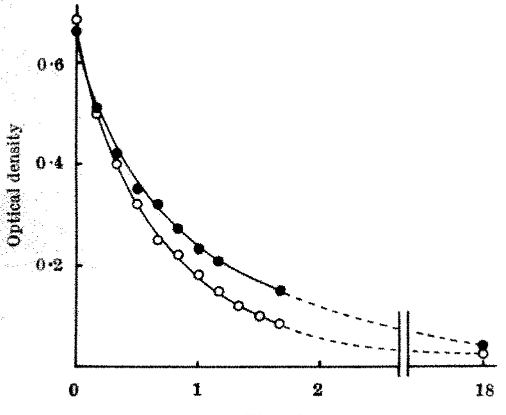

Fig. 1. Digestion of mucopeptides prepared from *E. coli B* and *M. lysodeikticus* by lysozyme. The mucopeptides were suspended at a concentration of 1·5 mgm./ml. in 0·1 *M* phosphate buffer (pH 6·0) and incubated with lysozyme at room temperature. Optical density at 620 mμ was measured at intervals. ○, Values for *M. lysodeikticus* in the presence of 10 μgm./ml. lysozyme; ●, values for *E. coli* mucopeptide, in the presence of 100 μgm./ml. lysozyme. This high concentration of lysozyme was necessary because the mucopeptide from *E. coli* contained an inhibitor of the enzyme apparently introduced during preparation (see text)

To determine whether the method of extraction was likely to damage the mucopeptide, the whole procedure was applied to Gram-positive mucopeptides. The end-product was found to be identical with that obtained by the more conventional methods.

Table 1 shows that the mucopeptides isolated from the five strains of *E. coli* so far examined are virtually identical, and the relative proportions of glutamic acid, alanine, and glucosamine are similar to those found in the mucopeptide of *Staph. aureus* 524. These values, and those for mucopeptides from four other strains of micrococci (see Rogers and Perkins[11]), have been included. It is apparent that, in the latter group, there is much more variability, and an even greater scatter has been found in the walls of lactobacilli[12].

The mucopeptides from *E. coli* were examined for sensitivity to lysozyme, and found to contain an inhibitor of the enzyme probably introduced in the preparation. 1 mgm. of mucopeptide contained sufficient inhibitor to inactivate 10–20 μgm. of lysozyme. However, if sufficient enzyme was added to overcome the inhibiton, there was rapid digestion of the mucopeptide accompanied by a fall in optical density of more than 90 per cent. This is similar to the reduction in optical density found with the mucopeptide of *Micrococcus lysodeikticus* (see Fig. 1).

It thus appears that the cell walls of *E. coli* contain a mucopeptide which, in its composition and its sensitivity to lysozyme, resembles those of the Gram-positive bacteria. The main difference seems to be that whereas the latter have been found to contain either diaminopimelic acid or lysine, the coliform mucopeptides contain both. This conclusion is supported by the fact that lysine increases proportionately with the diaminopimelic acid at each stage of the purification.

ENTOMOLOGY

A Species of *Tetranychus* Dufour (Acarina) from Uganda

RECENTLY, Baker and Pritchard[1] described certain tetranychoid mites from Africa, among which they listed *Tetranychus cinnabarinus* (Boisd.) and *T. telarius* (L.). Their work embraced a study of preserved material from Namulonge, Uganda, which they ascribed to the former species. The two species mentioned, together with others, have for long been the subject of controversy and have been included in the '*telarius* complex' by authors.

Boudreaux[2] produced evidence, from Nearctic specimens, of a series of constant morphological differences in both males and females whereby the components of the '*telarius* complex' could be separated. Baker and Pritchard applied his principles to their Ethiopian material. Thus the adult female of *T. cinnabarinus* is said to possess lobes on the dorsal integumentary striæ of the hysterosoma which are all semicircular or triangular (Fig. 1, enclosed by circle), whereas those of *T. telarius* are said to be mostly wide (Fig. 1, enclosed by square). Fig. 1 is a photograph of the dorsal integument of the hysterosoma of a typical adult female (feeding stage) of a species of *Tetranychus* commonly found on cotton at Namulonge. With this mite it is possible to follow the series of keys of Baker and Pritchard as far as couplet 9 in the key to species of *Tetranychus*; but at this point neither the name *T. cinnabarinus* nor *T. telarius* can be applied to it since it apparently possesses the integumentary characters of both species. The portion of integument figured displays 80 semicircular or triangular lobes and 30 wide ones; thus neither are they wholly of the former type nor mostly of the latter.

The conformation of the apex of the ædeagus of males of the Namulonge species presents a further anomaly. Baker and Pritchard, again following Boudreaux, described the apex of the ædeagus of of *T. cinnabarinus* as having a somewhat rounded anterior development, an angulate dorsal margin and an axis which forms a slight angle with the axis of the shaft. The drawing which accompanied their description agrees closely with Fig. 2 presented here (type *A*). On the other hand, *T. telarius* is said to have an ædeagus with the anterior development acute, the dorsal margin rounded and the axis parallel to that of the shaft. Fig. 3 represents this type of ædeagus (type *B*). However, Figs. 2 and 3 are photographs of two males of the Namulonge species which were born on the same day of the same female parent, by arrhenotokous parthenogenesis. The female, a typical adult (such as that described above) was isolated on emergence from the deutonymph and the male progeny produced were themselves reared in isolation. Apart from the morphology of the ædeagus, both mites were identical so far as could be observed. Since haploid males are produced in arrhenotoky, it is tempting to assume that ædeagi of types *A* and *B* appear as a result of a simple segregation of the members of a pair of allelic characters in the female, but insufficient material has been examined to establish the ratio in which the two types occur, nor is it possible to state unequivocally that no intermediate form is found.

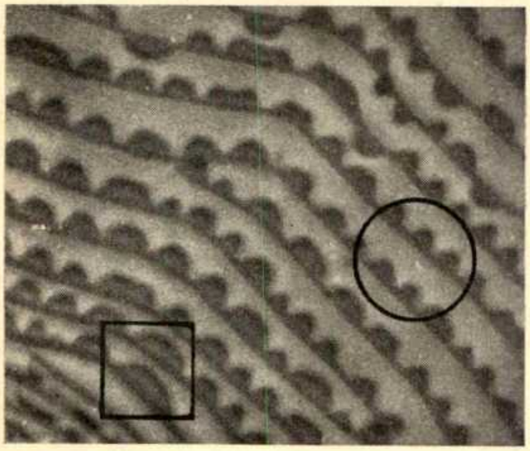

Fig. 1. Dorsal integument of adult female in region of right anterior dorsocentral hysterosomal seta

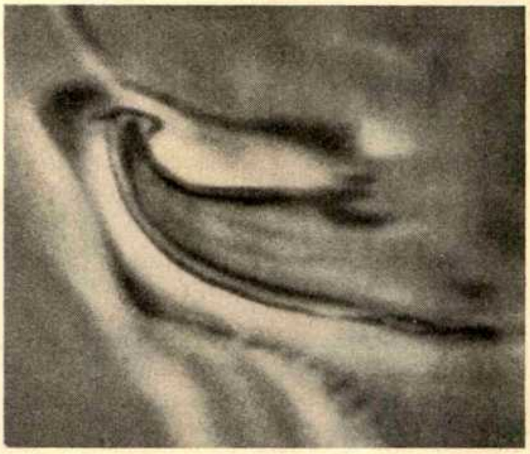

Fig. 2. Lateral view of ædeagus of adult male, type *A*

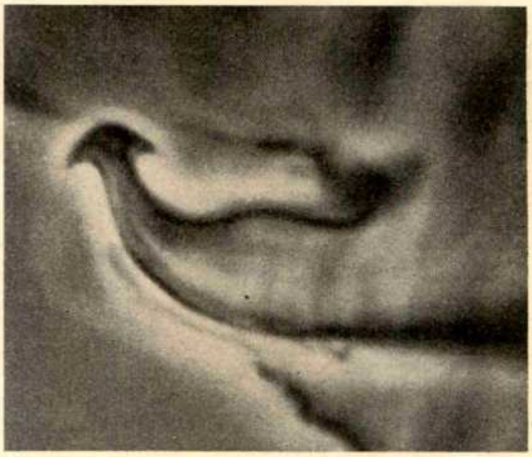

Fig. 3. Lateral view of ædeagus of adult male, type *B*

It is concluded that the means evinced by Boudreaux for the micromorphological separation of the components of the '*telarius* complex' may not be readily applied to all Ethiopian forms before a comprehensive study of the living material has been undertaken.

Specimens figured here were mounted from life in Hoyer's medium, photographed by Zeiss phase-contrast apparatus at 1,000 diameters and afterwards enlarged to 3,750 diameters.

VIROLOGY

Centrosema Mosaic: a Plant Virus Disease transmitted by both Aphids and Plant Bugs

INVESTIGATIONS have been carried out in Papua and New Guinea on a previously undescribed virus disease, *Centrosema* mosaic, which infects several tropical legumes.

The virus is transmitted mechanically, by *Cuscuta campestris* Yuncker, by two aphid species, *Brachycaudus helichrysi* (Kltb.) ? variety *warei* Theob. and *Aphis gossypii* Glov., and by two species of plant bugs of the genus *Nysius* (Table 1).

Table 1. INSECTS CAPABLE OF TRANSMITTING *Centrosema* MOSAIC VIRUS TO *Crotalaria anagyroides* H.B.K.

Insect	Insect form	No. of insects per plant	Proportion of plants infected
Aphididae			
Brachycaudus helichrysi var. *warei*	apterae	10	20/20
Aphis gossypii	apterae	10	6/20
Lygaeidae			
Nysius sp. (green)	winged	20	10/60
Nysius sp. (brown)	winged	20	38/60

It is not usual for a plant virus to be transmitted by both an aphid and a plant bug. *B. helichrysi warei* is able to transmit *Centrosema* mosaic after an access feeding period of 12 min. and remains infectious for 48, but not for 72 hr.; pre-access starvation increases the efficiency of transmission. These facts suggest the virus is transmitted in a non-persistent manner[1]. Winged females, wingless females and first and second instars of *B. helichrysi* var. *warei* are all capable of transmitting the virus.

Though *Aphis gossypii* can transmit the virus under laboratory conditions, it is probably not a natural vector as it has not been recorded feeding on *Crotalaria* spp. or *Centrosema pubescens* Benth., in the field.

Nysius spp. are able to transmit *Centrosema* mosaic to *Crotalaris anagyroides* after an access feeding period of 2 hr. and within a test feeding period of 24 hr.

The virus naturally infects and produces mosaic symptoms on *Centrosema pubescens*, *Crotalaria anagyroides*, *C. goreenis* Guill. and Perr., *C. retusa* L., *C. mucronata* Desv., *Calopogonium mucunoides* Desv. and *Desmodium distortum* (Aubl.) Macbride. The virus can also be mechanically transmitted to *Crotalaris juncea* L., *C. spectabilis* Roth., *C. incana* L., *C. intermedia* Kotschy, *C. lanceolata* E. Mey., and *C. usaramoensis* Baker F., and produces mosaic symptoms in all these hosts. *Stizolobium deeringianum* Bort. exhibits a pale greenish-yellow chlorotic spotting of the first set of trifoliate leaves following inoculations of the first true leaves with infective sap; subsequent leaves show mosaic symptoms which are systemic and persistent. The virus failed to infect *Phaseolus vulgaris* L., *P. mungo* L., *P. aureus* Roxb., *P. lunatus* L., *P. calcaratus* Roxb., *Vigna sinensis* (L.) Savi, *V. unguiculata* (L.) Walp., *Vicia faba* L., *Pisum sativum* L., *Medicago sativa* L., *Canavalia ensiformis* DC., *Datura stramonium* L., *Nicotiana tabacum* L., *N. glutinosa* L., *Lycopersicum esculentum* Mill., *Petunia hybrida* Vilm., *Cucumis sativus* L., or *Chenopodium amaranticolor* Coste and Reyn. following mechanical inoculation. The virus is inactivated after an exposure of 10 min. at 58° C.; at a dilution of 1 in 2,000, and after an exposure of 6 hr. at a room temperature of 28° C.

Further details of these investigations will be published elsewhere.

We acknowledge with appreciation the identification of the insect vectors by Dr. V. F. Eastop of the British Museum, and help given by Dr. M. F. Day of the Commonwealth Scientific and Industrial Research Organization, Canberra.

GENETICS

A Dominant Gene for Renal Adenomas in the Rat

FAMILIAL renal adenomas in the rat have been described in a previous report[1]. They usually occurred as multiple tumours and were bilateral. The tumours were simple cysts, papillary cystadenomas, solid eosinophile adenomas or solid basophile tubular adenomas. They varied in size from barely visible to large growths which included almost the entire kidney (Fig. 1). The material consisted of a number of individuals from a line of Wistar rats maintained in this laboratory, indicating that the condition was genetically controlled.

The breeding of these animals is a laborious process as they have to be opened and inspected to determine the presence of tumours. Males are inspected through a mid-abdominal incision while the kidneys of females are inspected through dorsolateral incisions as they frequently failed to care for their litters after abdominal operations. Furthermore, although

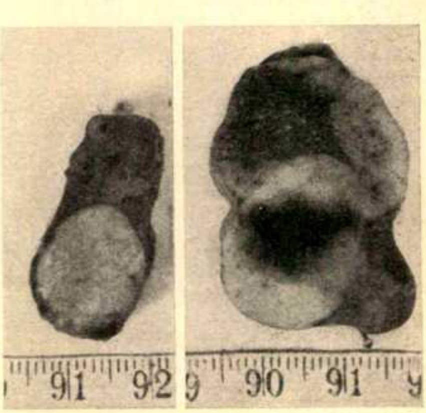

Fig. 1. Longitudinally bisected left and right kidneys of a female with large bilateral tumours

tumours have been found macroscopically in rats as young as five months, they are not usually readily detectable until 10 or 12 months of age, and even then only as small cysts which later develop into solid tumours.

The genetic analysis was begun with a single-tumour male, one of a litter of six, three of which were normal and three had tumours. The mother was tumour-bearing and the father normal. This male was outcrossed to six albino females from a closed laboratory population after having failed to produce any offspring with his three sisters.

A total of 106 F_1 animals was obtained from this outcross, 64 ♀♀ and 42 ♂♂. The inspection and microscopic examination of this first generation have been completed.

A complete post-mortem examination was made on all the F_1 animals, including microscopy of a number of organs, especially the lungs. The types of renal tumours observed are the same as those previously described. In some of them the microscopic picture resembles carcinoma with atypia of the cells and apparently invasion of the surrounding renal tissue. No invasion of the blood vessels has been observed, however, and no metastases have been found in any of the animals in spite of careful examination. The skeleton has also been examined by X-rays in some animals with large tumours, with negative results.

Seventeen of the F_1 animals died too young to be included in the material, leaving a total of 89 F_1 progeny. These were killed or died at ages varying from 19 to 24 months, and the kidneys of all were examined microscopically. All the animals classified as tumour-bearing were verified histologically. One animal macroscopically classified as normal was found to have an incipient tumour on microscopic examination: otherwise there was complete agreement between the macroscopic and the microscopic diagnosis. The results of this classification are presented in Table 1.

Table 1. Histological Diagnosis of Renal Adenoma in F_1 Progeny from a Single Tumour-bearing Male outcrossed to Six Unrelated Females of a Different Strain

	Tumour	Normal	Tumour (per cent)
♀♀	22	31	41·5
♂♂	15	21	41·7
Total	37	52	41 6

This is fairly close approximation to a 1 : 1 ratio.

In order to eliminate the possibility that there might be genetic factors involved in tumour development in the albino strain from which the mothers of the first generation were derived, one of the F_1 tumour males was outcrossed to 20 females of an entirely unrelated strain of hooded rats. Although the examination of all these progeny is not complete, the numbers are sufficiently large to confirm the correctness of the assumption that a single dominant gene determines the development of the tumours. These animals have not yet been examined histologically but the preliminary results of macroscopic examination of 113 progeny from this outcross are: 13 tumours, 19 cysts, 31 doubtful and 50 normal. In this case the sire is known to be a heterozygote, while the original sire of the F_1 might have been a homozygote as it was not possible to trace its ancestry with sufficient accuracy to eliminate the latter possibility.

An F_2 has been obtained by crossing inspected F_1 tumour males to F_1 females which had not yet been inspected. As the tumour females produce few and small litters, only 20 F_2 rats from such matings have so far been inspected at ages of 10–15 months, revealing 4 tumours, 4 cysts, 5 doubtful and 7 negative. This is a somewhat higher ratio of tumour animals than in F_1, but the material is still too small to calculate any ratios, and it is not yet known whether the homozygote is viable.

No correlation has been found between tumour development and sex, nor does there seem to be any influence of number of pregnancies on tumour development in females. The tumours in the F_1 animals were graded for number and size to determine whether there was any correlation between grade and sex; but the results were negative.

Further experiments are being carried out to determine the pathogenesis of the tumours.

HISTORY OF SCIENCE

Origins of the Copernican Revolution

The results of the 'Copernican Revolution' have been well described by historians of science. Less has been said about the origins of this revolution; that is, the problems and facts leading Copernicus to a conviction of the physical truth of the Earth's daily rotation and of its annual revolution around the Sun. I have developed a conjecture on this problem which will doubtless prove incorrect when closer study of the relevant sources is made, but which at least directs attention to a natural series of scientific problems, and which is based on Copernicus's own recollections of his early work.

Rheticus, the disciple of Copernicus in the latter's old age, gave in his *Narratio Prima*[1] a list of six principal reasons "why we must abandon the hypotheses of the ancient astronomers". The form of these ensures that they were taken from Copernicus himself. Of the six, the third, fourth and fifth have no surprises, relating to apparent planetary distances, uniform circular motion and economy, respectively. The sixth invokes the rule "that the order and motions of the heavenly spheres agree in an absolute system" and cites the non-observance of this rule by earlier astronomers as a cause of the bad state of the astronomy of the time. The first and second reasons must be quoted in full:

"In the first place, the indisputable precession of the equinoxes, as you have heard, and the change in the obliquity of the ecliptic persuaded my teacher to assume that the motion of the earth could produce most of the appearances in the heavens, or at any rate save them satisfactorily.

"Secondly, the diminution of the eccentricity of the sun is observed, for a similar reason and proportionally, in the eccentricities of the other planets".

These 'reasons' indicate that Copernicus was not exclusively concerned with the problem of short-range predictions of the planetary positions, although this is the only part of his work which has been popularized by historians. Further evidence for a concern with long-term variations comes in the prefatory letter of the *De revolutionibus*. There, first in his list of reasons for thinking of a new method for astronomy, is: "the mathematicians are so unsure of the movements of the sun and moon that they cannot even observe or explain the length of the seasonal year"[2].

It was almost universally believed, from early Islamic times to the sixteenth century, that both the rate of precession (motion of the fixed stars in longitude) and the length of the year were variable. Other parameters of basic astronomical theory were also considered variable (see the foregoing reasons), but I do not take them into account in my present work. A full understanding of these variations was considered necessary for any long-term prediction of the planetary positions, or of eclipses, and for calendar reform. This last was not a trivial task, for one cannot get the true mean of a quantity of unknown variation by averaging over an arbitrary interval. Moreover, the Christian calendar is lunar as well as solar, because of the definition of Easter; this made the problem more delicate. An important part of Copernicus's work was the institution of method in the study of these problems, which had not been treated by Ptolemy. It was for his achievements in these problems that he was called "the restorer of astronomy" by such later astronomers as Clavius. In actual fact, both the precession and the length of the year are constant, and both pseudo-problems died suddenly at the end of Copernicus's century. This is one cause for their neglect by historians. The other is that, from Galileo onwards, debate was centred on the physical and cosmological implications of the Copernican system rather than on the details of his mechanisms.

In my conjecture, I use the 'reasons' as indications of problems, and take a (supposedly) hard fact from the *Commentariolis*[3], written by Copernicus early in his career. This is, that from past records it appears that while the equinoctal year is variable, the sidereal year is constant. This has interesting implications for the choice of the fundamental space-time reference frames for positional astronomy. To explain 'precession', astronomers in the Ptolemaic tradition had assigned a slow but variable motion to the sphere of the fixed stars, a rotation about the pole of the ecliptic. (This was, of course, superimposed on the daily rotation, which was common to all the pre-Copernican theories.) The fixed point of zero celestial longitude was taken at one of the intersections of the great circle of the ecliptic with the extension of the Earth's equatorial plane; and time was measured by the Sun's passage through that point—the equinoctial year.

If, as Copernicus advocated in the *Commentariolis*, we change the definition of the standard year from equinoctal to sidereal (measured by the Sun's return to a given fixed star), an anomaly appears. For then it would be against an irregularly moving space frame (the sphere of fixed stars) that the motions defining uniform time would be measured. This contradicts all principles of harmony in the celestial motions, and such a system cannot serve as a fundamental space-time reference frame for astronomical science. Hence we need a different set of relative motions of the elements of the universe. (I should add here that the justness of the 'sidereal' measure of uniform motion was supported by other slowly varying parameters, or so appeared to Copernicus when he wrote the *Commentariolis*.)

One solution lies in a modification of a theory propounded by Copernicus's teacher, Domenicus Maria de Novara. This was that the Earth's equatorial plane is in motion; it was advanced to explain a supposed change of terrestrial latitudes (measured by the elevation of the pole) since antiquity. Giving the Earth's axis a slow conical motion (the 'Third Motion' of the mature Copernican theory) would free the stellar sphere of its trepidations, and give a harmonious reference-frame with 'sidereal' measures of space and time. It would also explain perfectly another fact reported by Copernicus in the *Commentariolis*: over the ages, a longer equinoctal year had coincided with a slower rate of precession.

But if Copernicus got this far, he then encountered a very serious problem: if this motion occurred, then the direction of the pole of rotation of the heavens, as seen by an observer, would have suffered an impossibly great change since antiquity. My conjecture rests on Copernicus getting this far with the problem, and then taking the only way out which would keep harmony in the heavens: letting the Earth rotate on its axis, while the axis performs the very slow conical motion. With this solution, the problem of the varying direction of the pole disappears. The principle behind the difference between the two solutions is that the finite rotations of a sphere do not commute.

My conjecture thus takes me to the first half of the 'Revolution'. Its extension to the annual revolution is something on which I have no ideas. Even this much bears on Copernicus's conviction of the truth of his theory, in spite of its physical, cosmological and theological difficulties. Sun and circle worship, and mathematical elegance, play their part, but a belief in the rationality and intelligibility of God's heavens may have been crucial.

There are two obvious objections to the principle of this conjecture. The first is that it requires Copernicus to have used two sets of false data (varying length of tropical year, and varying rate of precession), in such a fashion as to get consistent results, and without realizing their systematic connexion. This is easy to explain, for one and the same observational error (misreading the declination of the Sun, and hence misplacing the celestial equator) is responsible for both; orders of magnitude of observation error (5′), and errors of time and precession rate, work out correctly. There is also the fact that Copernicus made no mention of the precession problem in the *Commentariolis*, either in the text or in the introduction. This is not surprising, for at the time of writing it he had not worked out a precise mathematical theory of the 'Third Motion'. It is quite likely that Copernicus was able to work out the heliostatic equant-free planetary models with ease, using the geostatic equant-free models of Ibn Al-Shatir[4] But on those problems which had engaged and persuaded him "in the first place", he would hold back his solutions until they could stand up to detailed criticism.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, March 13

Institution of Mechanical Engineers, Industrial Administration and Engineering Production Group (at 1 Birdcage Walk, Westminster, London, S.W 1), at 10 a.m.—Informal Discussion on "Human Capabilities and Limitations in Industrial Operations".

British Society for the Philosophy of Science (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Karl Menger : "A Counterpart of Occam's Razor".

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Town Planning and Electrical Requirements".

Society of Chemical Industry, Agriculture Group (joint meeting with the Surface Activity Group, at 14 Belgrave Square, London, S.W.1), at 5.30 p.m —Mr. G. H. Cashen : "Electric Charges on Clays".

University of London (at King's College, Strand, London, W.C.2), at 5.30 p.m.—Prof. Marcel Simon (University of Strasbourg) : "Origins and Eschatology".* (Further lecture on March 14.)

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Mr. C. E. Engel : "Photography in Medicine" (Cantor Lecture).

Tuesday, March 14

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

Institution of the Rubber Industry, London Section (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 5.30 p m.—"The Union of Rubbers and Plastics", speaker from Polymer (U.K.), Ltd., 7 p.m.—Mr. C. H. Leigh-Dugmore : "Light Microscopy of Black-Loaded Rubber" ; Dr. E. H. Andrews . "Electron Microscopy of Black-Loaded Rubber".

University of London (in the Gustave Tuck Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. G. D. Sims : "Thermionic Generation".* (Fourth of five lectures on "Generation of Electricity without the Use of Rotating Machinery".)

Institution of Electrical Engineers, Education Discussion Circle (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "New Routes into National Certificate and Technician Courses", opened by Mr. H. W. French.

Wednesday, March 15

Royal Microscopical Society (at Tavistock House South, Tavistock Square, London, W.C.1), at 10.30 a.m.—Symposium on "Applications of Interference Microscopy".

Royal Institute of Chemistry (joint meeting with the Institute of Physics and the Physical Society and the Institute of Biology, in the William Beveridge Hall, Senate House, University of London, W.C.1), at 2 p m —Symposium on "The Soil ; Problems Raised by its Use and Misuse".

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Dr. S. Tolansky, F.R.S. . "The Folk Lore and History of Diamond".

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Dr. W. L. Godson · "Total Ozone and the Middle Stratosphere Over Arctic and Sub-arctic Areas in Winter and Spring".

Royal Society of Medicine, Comparative Medicine Section (at 1 Wimpole Street, London, W.1), at 5 p.m.—Meeting on "Hormonal Control of Fertility in Man and Animals".

Institute of Petroleum (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. A. J. Groszek and Mr. D. J. Palmer . "Surface-Active Compounds in Lubricating Oils".

Institution of Electrical Engineers, Supply Section (at Savoy Place, London, W.C.2), at 5.30 p m.—Discussion on "Magneto-Hydrodynamic Generation of Electricity" opened by Dr. P. L. Davies and Dr. D. J. Harris.

Institution of Electrical Engineers, London Graduate and Student Section (joint meeting with the Graduate and Students Sections of the Institutions of Civil and Mechanical Engineers, at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 6.30 p.m.—Prof. Sir Harrie Massey, F.R.S. · "Space Research".

Society of Instrument Technology, Data Processing Section (at 26 Portland Place, London, W.1), at 7 p.m.—Symposium on "Burst Slug Detection in Nuclear Power Stations".

British Psychological Society, Social Psychology Section (in Room 425, Birkbeck College, Malet Street, London, W.C.1), at 8 p.m —Mr Joseph Trenaman : "Television and Political Images".

Thursday, March 16

Institute of Physics and the Physical Society, Optical Group (at 47 Belgrave Square, London, S.W.1), at 2.30 p.m.—Annual General Meeting.

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Meeting for the Election of Fellows. 4.30 p.m.—Mr. F. P. Bretherton and Lord Rothschild, F.R.S. . "Rheotaxis of Spermatozoa" ; Mr. D. J. Crisp and Mr. A. J. Southward : "Different Types of Cirral Activity of Barnacles with special reference to Sessile Species".

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. F. R. Keogh : "On a Problem of Hardy and Littlewood concerning Rearrangements".

British Institution of Radio Engineers, Electro-Acoustics Group (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. S. Welldon : "Transistorized Tape Recorders".

Institution of Electrical Engineers, Utilization Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. D. S. Farr, Mr. H. C. Hall and Dr. A. L. Williams : "A Dynamic Model for Studying the Behaviour of the Overhead Equipment used in Electric Railway Traction".

Society of Chemical Industry, Road and Building Materials Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. J. A. Reis, Miss Barbara E. Sabey and Mr. J. G. James : "White Line Road-markings and Light Coloured Road Surfaces".

Association of Clinical Biochemists (in the Lecture Theatre, Royal Free Hospital Medical School, Hunter Street, London, W.C.1), at 7.30 p.m.—Prof. H. B. Collier · "Recent Advances in Red Cell Chemistry".

Chemical Society (at Burlington House, Piccadilly, London, W.1), at 7.30 p.m.—Prof. A. N. Terenin : "Change Transfer in Organic Solids, Induced by Light" (Centenary Lecture).

Royal Society of Tropical Medicine and Hygiene (at the Royal Army Medical College, Millbank, London, S.W.1), at 7.30 p.m. —Laboratory Meeting. Chairman : Sir William MacArthur, K C.B.

Friday, March 17

Society for Water Treatment and Examination (in the Library, Royal Society of Health, 90 Buckingham Palace Road, London, S.W.1), at 9.30 a m.—Annual General Meeting. 10.30 a.m.—Symposium on "Application of Laboratory and Pilot Plant Studies to Full Scale Water and Effluent Treatment".

British Psychological Society, Occupational Psychology Section (in the Department of Psychology, Birkbeck College, Malet Street, London, W.C.1), at 1 p m.—Mr. R. B. Buzzard : "An Approach to the Classification of Working Environments".

Institute of Rural Life at Home and Overseas (at Friends International Centre, 32 Tavistock Square, London, W.C.1), at 1.15 p.m.—Mr. Peter du Sautoy : "The Ghana Community Development Programme".

Institute of Navigation (at the Royal Geographical Society, 1 Kensington Gore, London, S.W.7), at 5.15 p.m.—Captain V. A. M. Hunt . "The Long-Term Plan for Air Traffic Control".

Society of Chemical Industry, London Section (joint meeting with the Fine Chemicals Group, at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. L. M. Jackman : "The Use of Nuclear Magnetic Resonance in the Determination of Chemical Structure".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. R. S. Nyholm, F.R S. : "Magnetism and Chemical Architecture".

Saturday, March 18

Nutrition Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 10.30 a.m. —Symposium on "The Place of Food Science and Technology in the Campaign against Malnutrition".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned :

British Oil and Cake Mills Research Fellow (graduate in agriculture, agricultural science or pure science, preferably with honours) in the Department of Agriculture—The Professor of Agriculture, The University, Leeds 2 (March 20).

Senior Lecturer in Metallurgy—The Registrar, The University, Nottingham (March 24).

Vice-Principal (with high academic qualifications and teaching experience at a high level)—The Clerk to the Governors, Chelsea College of Science and Technology, London, S.W.3 (March 24).

Lecturer in Applied Mathematics ; a Lecturer or Assistant Lecturer in Pure Mathematics ; and a Lecturer or Assistant Lecturer in Pure or Applied Mathematics—The Registrar, The University, Hull (March 29).

Assistant Curator (with a university degree in biology and the Diploma of the Museums Association) in Natural History at the St. Albans City Museum—The Town Clerk, 38 St. Peter's Street, St. Albans, Herts (March 31).

Lecturer or Assistant Lecturer in the Department of Genetics—The Assistant Registrar (Science), The University, Edgbaston, Birmingham 15 (March 31).

Research Fellow in the Department of Geology—The Registrar, The University, Edgbaston, Birmingham 15 (March 31).

University Demonstrator (with an honours degree in an appropriate science) in Agricultural Entomology—The Secretary, School of Agriculture, The University, Downing Street, Cambridge (March 31).

Head (graduate, with research experience in such fields as genetics, avian physiology, nutrition or embryology, and preferably experience in any field of poultry science) of the Poultry Research Section

—The Secretary, Wye College (University of London), near Ashford, Kent (April 1).

ASSISTANT LECTURER OR LECTURER IN ORGANIC CHEMISTRY at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 8).

ASSISTANT LECTURER IN CROP PRODUCTION—The Secretary, Wye College (University of London), near Ashford, Kent (April 15).

CHAIR OF PHYSICS—The Registrar, The University, Sheffield (April 15).

LECTURER (honours graduate) IN PHYSICS—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (April 15).

LECTURER IN MICROBIOLOGY; and an ASSISTANT LECTURER IN PLANT ECOLOGY IN THE DEPARTMENT OF BOTANY—The Secretary, University College, Gower Street, London, W C.1 (April 15).

LECTURER (preferably with experience in techniques dealing with root infecting fungi) IN BOTANY in the School of General Studies, Australian National University—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, April 15).

LECTURER or ASSISTANT IN PHYSIOLOGY—The Secretary of University Court, The University, Glasgow (April 29).

RESEARCH PROFESSOR IN NUCLEAR PHYSICS at the Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, May 1).

ASSISTANT TRIALS OFFICERS (preferably with practical experience in crop production) at Leeds University Farm, Headley Hall, Yorks, and at Seale-Hayne Agricultural College, Newton Abbot, Devon—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

PROFESSORS IN NUCLEAR PHYSICS, PHYSICAL CHEMISTRY, and HYDRAULIC ENGINEERING at the University of Peshawar—The Ministry of Labour (E.9), 26–28 King Street, London, S.W.1.

SENIOR LECTURER IN PHARMACOGNOSY; a SENIOR LECTURER IN PHARMACEUTICS; a SENIOR LECTURER IN PHARMACOLOGY; a LECTURER IN PHARMACEUTICAL CHEMISTRY; a LECTURER IN PHARMACOGNOSY; a LECTURER IN PHARMACEUTICS; and a LECTURER IN PHARMACOLOGY—The Registrar (Department D), Bradford Institute of Technology, Bradford 7.

AN EDUCATION FOR LIFE

ONE cannot help but feel a pang of sympathy for the youth of Britain to-day, gazing wide-eyed at the promised good (or goods) of our technological era. For it seems that the promised good may conceal and nurture a stifling evil.

In a report arising from the annual conference of the British Association for Commercial and Industrial Education*, critical surveys of recent policy recommendations in the field of education are presented. A final article summarizes these very aptly. It also proffers the happy conjecture that in A.D. 3000 posterity, on finding the Crowther, Albemarle, Carr, Jackson, McMeeking, Arnold and Anderson Reports in a casket, will experience a positive reaction to the energy and vision that was contributed to reassessing education for British youth.

The need for all this drastic reform springs from "a pressure quite outside the scope of public control, for its comes from outside . . . relates to the position of Great Britain among her trade competitors in other countries and the influence upon this of the system of higher education in this country". The old order of education whereby men were equipped with a "proper background" must yield to the new scheme of "indoctrinating them with certain forms of knowledge". They must now train to be of direct use to improve industrial processes and products. The knell of industry sounds ever shriller. Specialize, 'technologize' or perish. Hence, happily or otherwise, the country must eddy along in this sweeping technological turbulence.

In the teeth of the gale of change, perhaps we should try to preserve some degree of self-control, however, and not throw out existing good as so much ballast. To persuade the keenest minds of our generation into a technological career as the glowing imperative, could result in irrecoverable loss, particularly when it conflicts with natural tendencies in other directions. It is not fair. Some personalities, some minds, are suited to such a career, others not. Almost platitudinous, it may be said ; but then a platitude has been defined as a self-evident fact on which nobody acts.

To get the cream of British minds recruited to serve technology, we eulogize the virtues of applied science—'it performs everything by the surest rules and demonstrations'—in the Baconian sense. But we tend to gloss over the pedestrian qualities which are inescapably there. We show that the job of an applied scientist is to evaluate coefficients of the differential equations which physicists and mathematicians have formulated long before. This job is done using experiment, curve-fitting, statistical manipulation and computers when the mathematics is not amenable to implicit, analytical solutions. Useful and skilled activity, to be sure, but we may tend to glorify it as a creative process of the highest order, forgetting that what one technologist learns to manipulate, another can. Our unbridled enthusiasm may lead us to believe that training a man to be a directly useful component in industry is the *raison d'être* of education. Perhaps we should be a trifle more restrained and tell those brighter youths, who wish to do creative work, that a career in technology is very often a consuming, grim grind and a quest for half-truths.

The educational system of a country is an expression of its national ideal. Despite the obloquy levelled against the British system from inside, one cannot deny that it has produced men eminently civilized and competent. Turn to the international arena, where the unfortunate East–West technocracies clash, and note the undisguised, fierce barbarism on one hand and the poorly disguised sentimentality and emasculation on the other. Then look at Europe, with Britain, and recognize quality. In the past, as now still, British education served to produce men who were literate, able to reflect, to judge and to converse. They understood the broad sweep of things. In a recent article*, Prof. M. W. Thring adduces that to-day "we have the much more concrete problem of making scientific laws seem exciting and interesting to a large proportion of our youth". What a pity that we must make these laws only seem so. Do we fall into inadvertent deception to serve the great-god, 'Technology' ? Must the "combustible material" in the minds of our youth (Prof. Thring's imagery) be made a burnt-offering to the avaricious deity ?

The British have always shown a proclivity to retain what they have proved good over centuries. Now we are beginning to distrust our judgment. Trans-Atlantic fever for uprooting itself fascinates : "In America industrial management will very often scrap plant just because something newer has come along. . . . We keep old plant because we are fond of it. . . ." We gaze bewitched at the Kremlin and Peking ; the Labour University at Kiangsi has 50,000 students and there are 1,065 such institutions in China. What a paradisial plethora of technologists there must be. Instead of being naively deceived as to what constitutes quality, we should pause and consider where the fount of fundamental scientific ideas springs from, and then note the educational environment which has given rise to these meditative, inspired minds.

We have indeed a grave responsibility to British youth. Let not the national ideal be to turn out mass-produced stereotypes who cannot converse or use language properly except as the jargon of their particular narrow occupation, who seek only to speak of facts, dull though these may be, who cannot stand up to dialectical encounter, who show distinct discomfort when ideas, feelings and imagination are introduced. Let us respect the individual. Instead of forcing or trapping the talented into a technological constraint, let us rather guide them wisely toward, and allow them to flourish in, the environment to which they naturally would incline.

---

* Policy in Perspective Report of the BACIE Annual Conference held at Cambridge, 22–24 September, 1960. Pp. 126. (London: British Association for Commercial and Industrial Education, 1960.) 10s.

* *The Advancement of Science*, Vol. 17, No. 69; January 1961. Pp. 456–460. (London: British Association for the Advancement of Science, 1961.) 7s. 6d.

Amid the frenzied pressures of this decade, it seems appropriate to refer to the Earl Grey Memorial Lecture (*Today and Yesterday*) delivered by G. M. Young. He felt that the duty of a State is to build up a nation which, in the Aristotelian sense of the educated, the civilized mind, knows what questions to ask and what answers to be satisfied with. Before the passage from adolescence to manhood is complete, there should be implanted in the child an appreciation of domestic coherence, sense of stock, significance of the hearth and of the society which goes on and on for ever and is by nature the home. He should be guided in his education from the dogmatic stage, where there is passive acceptance, to the dialectical, where the infinite variety of interpretations of life is grasped. Here he, who is trained in a purely technical sense, often fails abysmally. Imbued with the rules and procedures of his precious doxology, anything outside his little province is scarcely credible, if at all comprehensible.

Mr. Young believes that people cannot be educated at a much greater rate than their families are being civilized. No doubt, however, if proper education becomes more and more available, greater numbers will emerge from homes where true intellectual sympathy reigns. With the canons of science and the art of reasoning so generally understood, the relationship between the learned and the ignorant would be one of confidence. So, even in the new order, Britain will preserve that sense or instinct of continuity; each generation being duly trained to step into the succession when the time comes. In effect, Britain would thus rear a democracy which was also an aristocracy. If no longer a great power, let us strive to be a good one.

So, beset by the dominant influences of the world to-day—fierce, passionate despotism on one side and sick, surrealistic anarchy on the other—Britain must eschew imitation. Instead, may the good bequeathed by the experience of ancestry be recognized and retained. May it continue, with Wordsworthian sentiment, "To make the gift of life more valuable and the men more worthy of the gift".

INTRODUCTION TO PLANT ANATOMY

Anatomy of Seed Plants

By Prof. Katherine Esau. Pp. xvi+376. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1960.) 56*s*. net.

IT is essential for all students of botany to make themselves well informed about the structure of plants. This applies to those who will ultimately become specialists as well as to those whose knowledge of botany remains more general. In spite of the importance of plant anatomy it is remarkable how seldom we find that a student's knowledge of this branch of botany reaches the same standard as that which he attains in others. This situation probably arises, at least in part, because there are so few botanists who are actively engaged on research into the classical aspects of plant histology, and teachers of the subject tend to be purveyors of second-hand information and lack the inspiration that can come only to those fighting in the front line to acquire new knowledge. Prof. Esau has, for many years, been actively engaged on plant anatomical research. She can therefore speak as one having authority based on first-hand experience, and, in the book under review, she does so in clear and simple language. She illustrates what she has to say with line drawings, photomicrographs and a few electron micrographs. These illustrations, of which only a few have been supplied by other authors, are well chosen and of quite outstanding quality. These facts will cause no surprise to the many students and research workers who are already familiar with Prof. Esau's larger text-book entitled *Plant Anatomy* (John Wiley and Sons Inc., 1953), which has come to be accepted as one of the best books of its kind in the English language. The high price of the larger book has, however, undoubtedly prevented it from being as widely used among impecunious students as it deserves to be, and the shortened version which Prof. Esau has now produced, although the price is still fairly high, can be sure of a ready welcome. Indeed, it is to be hoped that the carefully selected anatomical information which it contains will be mastered by all students of botany and that it will serve as the terra firma of fundamental knowledge on which their subsequent studies may be securely grounded.

The book is divided into 22 chapters. The subject is treated mainly from the developmental point of view and deals not only with the cells and tissues of adult organs, including those of flowers, fruits and seeds, but also treats the plant at all stages from the embryo to maturity. There are indications of how the structure of the plant is related to ecological conditions, to taxonomy and to physiology. There is little to be found to criticize in a book of such undoubted excellence and that is so well produced and printed, but the reviewer feels that the relationship of structure to physiological function could be usefully expanded. For example, where Prof. Esau is discussing phloem, on the structure of which she is indeed a leading authority, one is intrigued to read that the nature of the protoplasts of sieve-tube elements and of the connecting strands in sieve areas must be understood before we can reach a satisfactory explanation of how food is translocated. It is also interesting to read that "the known characters of the protoplast do not wholly support any of the hypotheses advanced so far with regard to the (translocation) mechanism". Having had his appetite thus whetted, the reader may well feel that he would like to know more about Prof. Esau's views on this all-important topic; but perhaps the explanation is that she has thought it wise not to commit herself too far in an elementary text-book.

Selected bibliographies are given at the ends of the chapters, and the book contains an excellent and all-important glossary of anatomical terms. Such glossaries are very much needed, especially in these days, when there is often a lack of precision in the meaning of terms, when the language employed by wood anatomists is not always familiar to other anatomists, when pharmacognoscists sometimes tend to use terms in senses that do not always agree with those used in botany departments, and when electron microscopists and classical anatomists do not mean quite the same thing when they use a term as familiar as 'primary wall'. Most of the terms that Prof. Esau has adopted should be readily accepted by all, but botanists in Great Britain may be surprised to find the white- and yellow-coloured tissue in the rind of an orange referred to as the 'albedo' and 'flavedo' respectively.

Prof. Esau lays special emphasis on the unity and interdependence of the parts of a plant as revealed by developmental studies. This unity is further stressed in the introduction to this book where we read that: "The separation of the plant into organs can be made only approximately. It is impossible, for example, to draw a clear demarcation between the shoot and root and between stem and leaf, and the flower in many ways resembles the vegetative shoot. The internal structures, similarly, are not sharply delimited, and the categories of cells and tissues show much intergrading". How true this all is, and how helpful it would be if it were more generally recognized among botanists that Nature abhors distinct lines of demarcation. The classification of cells and tissues, like that of the plants themselves, is by no means easy.

In this book the author successfully vitalizes the whole subject, and the reader can scarcely fail to realize at the outset that he is being asked to consider cells and tissues in living organisms and not in dead corpses. It is to be hoped that this vital approach will stimulate a widespread desire among students to know more about this important aspect of plant science which is often so needlessly thought of as being dull.

C. R. METCALFE

AN ANATOMY OF GRASSES

Anatomy of the Monocotyledons

By C. R. Metcalfe. Vol. 1: Gramineae. Pp. lxi+731. (Oxford: Clarendon Press; London: Oxford University Press, 1960.) 84*s*. net.

METCALFE AND CHALK is a name as familiar to the botanist as Mrs. Beeton is to the cook and, like Mrs. Beeton, it contains a vast amount of information largely derived from first-hand observation.

The present work is another monument to the skill and indefatigable industry of Dr. Metcalfe, who once again puts plant anatomists and taxonomists in his debt.

The main part of this volume consists of a systemati account of the anatomy of 206 genera and 413 species of grasses which have been investigated by Dr. Metcalfe in the past ten years; to this is added information obtained from the literature about a further 139 genera, so that something of the order of half the genera in the family are considered. Since the genera of grasses, like those of most other families of flowering plants, do not fall readily into a linear sequence, an alphabetical order has, very sensibly, been adopted for this 'histological dictionary' section of the book. The bamboos are regarded as sufficiently distinct in their leaf anatomy to be treated separately after the grasses belonging to other tribes have been discussed. The merit of this arrangement is perhaps open to question, since there are genera, such as *Anomochloa* and *Pariana*, which have many bambusoid features, and the distinction between the panicoid and festucoid types of leaf seems to be almost as clear-cut as that between these types and the bamboos. There might therefore have been something to be said in favour of a completely alphabetical arrangement; this is, however, a minor point.

The introductory chapters on the general morphology of the grass plant and on anatomical characters and their value to the taxonomist provide both a basis for the understanding of the dictionary and an admirable summary and discussion of the detailed information. Dr. Melville is himself very cautious in considering the implications of his anatomical observations for taxonomy, but to one whose knowledge of grass taxonomy is slight and of anatomy even slighter they seem to be of the first importance. Some of them have already been incorporated in taxonomic works by Dr. C. E. Hubbard and others; no doubt the remainder will be speedily utilized.

In this connexion a particularly valuable service is performed in directing attention to genera such as *Danthonia*, which are anatomically heterogeneous, as the desirability of a re-examination of their floral morphology and an investigation of their chromosomes is clearly indicated.

In conclusion, mention must be made of two other excellent features of this book. One is the account of the fairly simple but not generally known methods used in preparing both fresh and dried material for microscopic examination, and the other is the beautiful drawings of the main types of structures described in the text.

One is left with an enhanced feeling of admiration for both the Gramineae and Dr. Metcalfe, and a pleasurable anticipation of further volumes on other families of Monocotyledons.

T. G. TUTIN

SURVEYS IN APPLIED MATHEMATICS

Elasticity and Plasticity

By Prof. J. N. Goodier and Prof. P. G. Hodge. (Surveys in Applied Mathematics, Vol. 1.) Pp. ix+152. 50*s*. net.

Dynamics and Nonlinear Mechanics

By E. Leimanis and N. Minorsky. (Surveys in Applied Mathematics, Vol. 2.) Pp. xii+206. 62*s*. net.

Mathematical Aspects of Subsonic and Transonic Gas Dynamics

By Lipman Bers. (Surveys in Applied Mathematics, Vol. 3.) Pp. xv+164. 62*s*. net.

(New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1958.)

THE great flood of papers in applied mathematics which now pours endlessly through scientific journals from individuals and research groups throughout the world makes it impossible for the practising mathematician to keep fully abreast with new developments, except in some special field in which he is himself working. It follows that surveys of recent work written by authorities in their respective subjects and intended for the mathematically literate reader who is not a specialist in that subject can be of great value. In particular, they serve to direct attention to ideas and methods developed in one subject which may have useful applications in another. The present volumes are good examples of such surveys. A particularly valuable feature of them is the special attention their authors have paid to recent Russian publications. Indeed, one of the most notable features of these surveys is the great volume and importance of the Russian contributions to most of the subjects discussed.

In the first part of the first volume of the series, Prof. Goodier describes some recent advances in the mathematical theory of elasticity. The most significant of these advances undoubtedly springs from the work of Muskhelishvili, and a great deal of the survey is devoted to his work. His early work on complex potential theory, leading to elegant and comprehensive methods of solving plane problems with prescribed boundary forces or prescribed boundary displacements, is briefly described. This is followed by a rather more detailed, though still condensed, discussion of Muskhelishvili's fundamental work in the theory of complex singular integral equations and the associated Hilbert problem. The solution of this problem using Plemelj's theorem provides a remarkably powerful method of solving mixed boundary value problems. The fundamental theory has of course been available for some years to English readers in J. R. M. Radok's translations of Muskhelishvili's two classical treatises, but there is also a considerable Russian literature on detailed applications to specific problems; the present survey gives a most useful summary of these applications. Other topics briefly dealt with include anisotropic elasticity, thermal stresses, contact problems and wave propagation. The theory of finite deformations is referred to but not described, since an excellent recent account of this is to be found in Green and Zerna's book.

The other part of Volume 1 is a discussion by Prof. Hodge on the present state of the mathematical theory of plasticity. Here the emphasis is rightly placed on the derivation of the fundamental principles and equations of the theory, rather than on methods of solution of specific problems, though one problem, that of a simply supported plate with various types of plasticity, is dealt with in detail as an illustration of the methods at present available; references are also given to a number of other problems. There is a very readable introduction to the general theory, and the postulated properties, such as perfect plasticity, piece-wise linear plasticity, kinematic and isotropic strain-hardening, etc., of various ideal substances are clearly defined. The plastic-flow laws are derived, and the inadequacy of any deformation theory for discussing many problems is emphasized. A short chapter is devoted to Russian contributions, but the very brief descriptions of these prove insufficient, at least to me, to indicate their value and significance.

The second volume of the series is also divided, the first part by E. Leimanis being mainly a discussion of the two celebrated problems in classical dynamics, (i) the motion of a heavy rigid body about a point and (ii) the three-body problem. There is also a chapter on exterior ballistics. Many of the investigations considered can scarcely be described as recent. The solutions of the special cases of the rigid body problem associated with the names of Euler, Lagrange and Kovalevskaya are discussed in some detail, and the investigations of Poincaré, Hess, Schiff and others on the existence of other solvable special cases are described. Almost all recent work relates to special cases, and no significant advance in the theory of the general motion is reported. The situation is not very different for the three-body problem. Little progress towards a general understanding of the problem can be discerned since Sundman's solution of 1912. Indeed, Prof. Leimanis devotes a considerable section to showing that Vernić's recent attempts (1952) to extend the validity of Sundman's solution to triple collisions have not been successful. More satisfactory progress has been made in studies of periodic and asymptotic solutions of both the restricted and the general three-body problem, and Merman's work in recent Russian papers on the problem of capture seems to be perhaps the most significant of recent advances.

In the second part an excellent introduction to the theory of non-linear oscillations is given by N. Minorsky, beginning with and largely based on van der Pol's equation $\ddot{x} + \mu(x^2 - 1)\dot{x} + x = 0$. The important topological concepts introduced by Poincaré, the identification of singular points in the phase plane with positions of equilibrium, limit cycles with stationary motions and so on, are adequately explained, and various approximate methods of solution of the equation $\ddot{x} + x = \mu f(x,\dot{x})$, where μ is small, are described. The radical change in character of the problem when μ is not small is emphasized, and the different methods of approach which have been tried in this case are reviewed. The important work of Cartwright and Littlewood on the conditions for existence of a periodic solution of van der Pol's equation is mentioned, but does not seem to have led to a practical method of solution. Another method of approach is the discontinuous theory of relaxations, analogous to the theory of shocks. This has been developed mainly in the U.S.S.R. by Chaikin, Lochakov and others, and seems at present to offer the most practical tool for applied problems.

In the third volume of the series Prof. Lipman Bers discusses certain mathematical aspects of subsonic and transonic gas-flow theory. He deals exclusively with steady irrotational flows and almost exclusively with two-dimensional problems. He places more emphasis on mathematical concepts and techniques than on specific physical problems, but gives some indication of recent practical methods and results. He devotes much of his discussion to the questions of existence and uniqueness of solution of various problems. Since the governing equations of compressible flow are non-linear and of mixed type, these questions involve some highly sophisticated mathematical arguments, and only recently has much progress been made in finding answers to them. Chapter 1 is a good introduction to the subject and describes the various approximations and modifications of the potential flow equation. Chapter 2 is concerned with the general theory of elliptic equations, quasi-conformal mapping and the theory of pseudo-analytic functions to which the author has himself made important contributions. Chapter 3 applies the results of this theory to subsonic flows. Tricomi's theory of mixed elliptic-hyperbolic equations is discussed in Chapter 4 and applications to transonic flow are given in Chapter 5. A short appendix is added on numerical methods. This volume is by no means easy to read, but it contains much of interest and value to the applied mathematician.

In conclusion, it may be said that these three volumes, though somewhat uneven in their degree of mathematical sophistication, achieve their purpose of providing a good overall picture of the present state of certain fields of study. They are well produced, and few misprints appear to have crept in, though some were noticed in the third volume.

A. T. Price

NEBULÆ, GALAXIES AND COSMOLOGY

Rival Theories of Cosmology

A Symposium and Discussion of Modern Theories of the Structure of the Universe. By Prof. H. Bondi, Dr. W. B. Bonnor, Dr. R. A. Lyttleton and Dr. G. J. Whitrow. Pp. xii + 61 + 12 plates. (London and New York: Oxford University Press, 1960.) 9s. 6d. net.

l'Exploration des Galaxies Voisines par les Méthodes Optiques et Radio-Électriques

Par Dr. Gérard de Vaucouleurs. (Collection "Évolution des Sciences", No. 13.) Pp. 156 + 18 planches. (Paris: Masson et Cie., 1958.) 1,600 francs.

Le Nebulose e gli Universi-Isole

Da Giorgio Abetti e Margherita Hack. (Biblioteca di Cultura Scientifica, No. 62.) Pp. x + 354. (Torino: Edizioni Scientifiche Einaudi, 1959.) 3,000 lire.

IN the autumn of 1959, the B.B.C. Third Programme broadcast a series of three talks on cosmology followed by a discussion at which the rival theories were debated. The short book *Rival Theories of Cosmology* is a direct outcome of these, the content being substantially the same as that of the talks.

Relativistic theories of the universe are discussed by W. Bonnor in the first chapter. This is followed by an account of the steady-state theory, the case being put by H. Bondi, one of the originators of the theory. Finally, R. Lyttleton explains his idea that the expansion of the distant galaxies may be due to the proton having a slightly greater numerical charge than the electron. The volume contains some good illustrations of galaxies, but the book would have been improved by the insertion of a short chapter on some of the observational aspects relevant to cosmology. The text does not presuppose any detailed knowledge of astronomy or cosmology, and within the limitations which are of necessity imposed by this restriction the ideas are put forward very clearly. The book is recommended to anyone who wishes to be introduced to some of the problems of cosmology.

L'Exploration des Galaxies Voisines has been written by an astronomer who has himself worked extensively in the field concerned. After a brief introduction to the nature and classification of galaxies, the problems of estimating extra-galactic distances are considered in some detail. Subsequent chapters deal with the luminosities, diameters, spectra, colours, rotation and masses of galaxies. In addition, there is a chapter devoted to the information about galaxies which has been obtained by means of radio astronomy. The text is well written in a logical sequence; the plentiful illustrations and diagrams are of a high standard. The author intends to write a second volume in which more general topics such as clusters of galaxies will be treated. There is a dearth of up-to-date books about galaxies, and it is to be hoped that the second volume is of the same standard as this first one.

The work by G. Abetti and Margherita Hack discusses planetary nebulæ, diffuse nebulæ and interstellar absorption before describing some of the structural and kinematic properties of the galaxy. The last chapters are concerned with galaxies in general and the rival theories of cosmology. The scope of the book covers a wide range of subjects which are in some cases rather indirectly connected with each other, and the planning of the volume leaves much to be desired. Despite this criticism, some of the individual description is quite good. The book contains some useful material which is not often found in accounts written for the non-specialist.

J. B. Alexander

VERSATILITY OF VACUUM

Progress in Vacuum Science and Technology

Edited by A. S. D. Barrett. Pp. iii + 160. (London and New York: Pergamon Press, 1959.) 70s.

IN recent years vacuum techniques have been introduced into a number of different industrial fields and this book will give the reader a good idea of some of them. The book contains six chapters, each dealing with a particular application and written by an expert in that field. There is also an introductory survey of education in vacuum practice at colleges in the United Kingdom. The contributions have been published as separate articles in the journal *Vacuum*.

Although the book-title includes "Science and Technology", the majority of the chapters are written from a technological rather than a scientific point of view, and are largely descriptive. That on problems in the valve industry does, however, touch on the basic theory more than most. The chapter on the gettering process in receiving valves includes a historical survey of developments leading to the modern type of barium getter. The gas clean-up performance of the latter is given, but the physics of the process is barely mentioned.

The applications of vacuum to metallurgy, fumigation and drying of medical and food products are in complete contrast to valve techniques. These chapters deal with the use of not-so-high vacua on a heavy engineering scale and make interesting and informative reading to those whose knowledge of vacuum is derived mainly from the standard textbooks. The final chapter, on molecular distillation, describes a number of vacuum stills, particularly those of Hickman, who has been largely responsible for recent developments in this field.

A book of this nature is unlikely to be exhaustive, and the most notable omissions are the recent work on ion-pumps and the production and use of ultrahigh vacua, which get only passing mention. The book is well produced and fairly free from misprints. Most chapters have an adequate bibliography; that on molecular stills in particular. Thus this book provides a useful survey of the industrial applications of vacuum, in a form suitable for a busy technologist to read.

R. O. Jenkins

A NEW THERMIONIC GENERATOR

By Prof. D. GABOR, F.R.S.

Department of Electrical Engineering, Imperial College of Science and Technology, London, S.W.7

IT has been known since the investigations of Irving Langmuir in the early 'twenties that the thermionic vacuum diode can be operated as a converter of heat into electric power, but with very poor efficiency owing to the minuteness of the currents. In recent years it was recognized that the efficiency could be raised to an economically interesting level if it were possible to compensate the electronic space charge by a sufficiently cheap supply of ions. Cæsium, with the lowest ionization potential of all the elements (3·9 V.) appeared the most promising, all the more as cæsium ions could be produced by the Langmuir–Kingdon effect, that is to say, by contact with the hot surface of materials with a work function exceeding 3·9 V. In the cæsium diode, as developed by R. W. Pidd *et al.*[1], also by K. G. Hernquist[2] and V. C. Wilson[3], cæsium vapour is ionized by contact with a hot electrode which can be either the emitter itself, or a third, hot electrode. The minimum cost per cæsium ion, taking into account the radiation losses of the hot surface, has been estimated as 100 eV., and as one cæsium ion can compensate the space charge of about 500 electrons, theoretically one ampere could be passed through such a diode at a cost of about 0·2 watt. The experimental figures are appreciably larger.

In the new thermionic device an experimental cost figure of 0·05–0·1 watt/amp. has been achieved, moreover not with cæsium, but with argon (ionization potential 15 7 V.) or with an argon–mercury mixture. Using cæsium, the cost could be reduced by a factor of 3–4, but it is doubtful whether it would be worth while to improve the efficiency further at the expense of the useful life of the device, which is likely to be much shortened by the chemically very active cæsium or other alkali metals.

The principle of the new device is illustrated in Fig. 1. The main discharge occurs between an emitter, which can be heated, for example, by flame gases through a ceramic envelope, and a collector electrode. For reasons to be explained later, it is essential to give the collector a large area relative to the emitter ; it is therefore realized as a cellular structure. The voltage drop in the main discharge space is of the order of a small fraction of a volt only, so that no ionization or excitation occurs in it, and in operation this space appears dark. All ions are supplied to it from an auxiliary discharge between a gauze or similar perforated structure and an auxiliary anode. In operation a small fraction of the electron current shoots out from the dark plasma in the form of fine electron beamlets through the meshes of the gauze, where an acceleration region is formed, with a drop just sufficient for ionization. Owing to the favourable focusing properties of the electric field, a large fraction of the ions thus formed returns through the meshes into the main discharge space. The flow of electrons and ions is illustrated in the left half of Fig. 1, but only schematically, just to illustrate that only a small fraction of the emitter current goes into the auxiliary discharge, while a large fraction of the ions find their way to the cathode. There is some experimental evidence that this is aided by reflexion of the slow ions at the walls of the collector, because increasing the surface of the collector by a cellular structure had a remarkably small influence on the auxiliary discharge required to maintain a certain emitter current. The question mark in the reflected ion path indicates our almost complete ignorance on the subject of the reflexion of very slow ions at surfaces.

It is very essential for the operation of the device that the auxiliary discharge has a positive characteristic, as only this enables thousands of tiny discharges in the meshes to operate in parallel. This is true for all inert gases and also for mixtures of argon and mercury up to a certain proportion of mercury. (For example, 2 mm. argon, with mercury saturated at 80° C.) In pure mercury the elementary discharges tend to have a negative characteristic, and instead of the operation as illustrated one then obtains an arc through a single mesh. In order to make the operation economical the meshes are made sufficiently wide so that the drop in the accelerating region exceeds the ionization potential only a little (80–120 wires per inch). As the anode drop at the auxiliary anode is negative, the total drop in the auxiliary discharge can be appreciably less than the ionization potential, for example, 10 V. in argon, only 7·5 V. in an argon–mercury mixture. The ions are therefore rather slow when they shoot through the gauze, and are slowed down further by collisions with gas molecules, so that they have little more than the gas temperature by the time they reach the cathode.

According to I. Langmuir's theory[4], slow ions coming from a plasma will compensate optimally the space charge of the electrons, emitted by a hot cathode, if the ion current is a fraction $\sqrt{m/M}$ of the electron current, where m is the mass of the electron, M of the ion. This ratio is 1 : 272 for argon, 1 : 494 for cæsium, 1 : 607 for mercury. Though Langmuir's theory was an excellent qualitative guide in the experiments, it might require some quantitative revision because the auxiliary currents in argon were in some experiments as small as 1/100 of the emitter current. Even if all the power in the auxiliary discharge were converted into ionization, this would give only about one ion for 160 electrons, and as the ionizing efficiency was certainly much short of 100 per cent and as some ions must have been lost in the gauze and at the walls, it appears very likely that the ion : electron ratio can be, in fact, better than Langmuir's optimum, again suggesting that there is some reflexion of slow ions.

The picture of the discharge derived from our experiments is illustrated in the right half of Fig. 1. The dark discharge space is filled with a dense plasma of remarkably small electron temperature. At low currents this is only a few hundred degrees in excess of the emitter temperature, indicating that the cathode drop is a few hundredths of a volt only, rising to a few tenths at large currents. As the current density can be of the order of an amp./cm.^{2}, the cathode sheath thickness must be of the order of

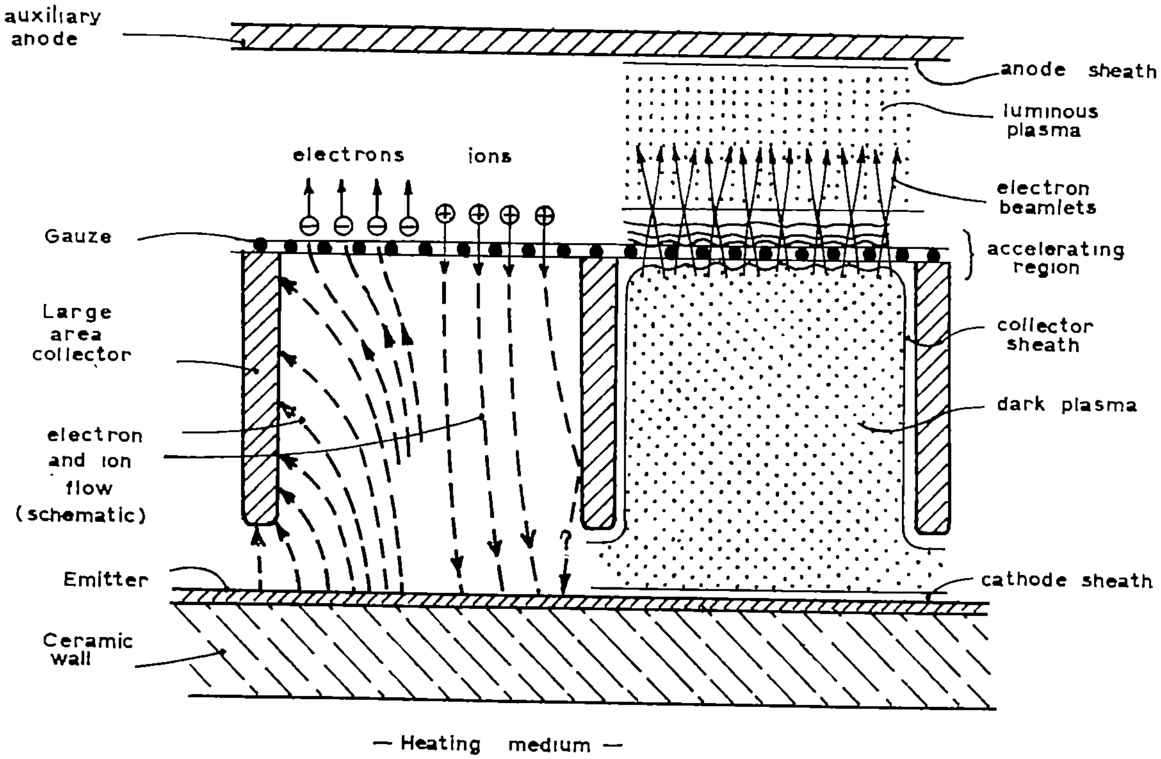

Fig. 1. Schematic section through thermionic generator

1μ. At small currents the plasma has a practically uniform potential; at higher currents a gradient develops. It is a fortunate circumstance that owing to the Ramsauer effect the cross-section of argon to electrons with energies of the order of a few tenths of a volt is very small, but even if it were zero the resistivity of a plasma, as estimated by Gvosdover[5] and by Spitzer[6], is not negligible. At the collector there is a negative drop in all circumstances which we have investigated, and this can be larger than the cathode drop, so that the total voltage drop in the gas space can be negative.

These conditions are further illustrated in Figs. 2 and 3. Fig. 2 is a diagram of the potential from terminal to terminal. As a typical example the emitter work function $\varphi_{\text{em.}}$ may be 2·5 V., the collector work function $\varphi_{\text{coll.}} = 1 \cdot 0$ volt, giving a nominal terminal voltage of 1·5 V. per element. Fig. 3 shows the voltage-current characteristics of the device, theoretically derived but well confirmed by experiments. The theory starts from the assumption that at small currents the discharge space is filled with a uniform, equipotential and, as regards the electron temperature, isothermal plasma. Consider first the case of zero potential difference between emitter and collector. In that case the same random electron current flows from the plasma to equal areas of the emitter or of the collector. The current density at the collector is equal to this random current, while at the emitter it is the difference between the saturated emission and the random current. It follows at once that at $V = 0$ the current is a fraction of the saturated emission current equal to the ratio of the collector area to the total area, that is to say, emitter plus collector. In the diagram it has been assumed that the collector area is three times the cathode area, hence at $V = 0$ the current is 3/4 of the saturation current. The saturation current is limited either by the thermal emission of the cathode, or by the ion supply. By Langmuir's rule the ion-limited current is $\sqrt{M/m}$ times the ion current, and will be proportional to it until thermal saturation is reached. This has been well confirmed by experiments, because it was found that the saturation currents were proportional to the currents in the auxiliary discharge, in any event at low values of the current. With oxide cathodes at high auxiliary currents there is no sharp limiting current because at ion supplies exceeding Langmuir's ratio there will be a non-zero electric field at the emitter, and in composite cathodes field-assisted emission is relatively important.

The same model of a uniform, equipotential and isothermal plasma applied to non-zero values of V gives a current characteristic $I(V)$ in the shape of a hyperbolic tangent function, with a subtangent $4kT/e$, where T is the electron temperature. This was verified, and the value of T agreed well with that obtained from Langmuir probes. At low currents, T was found to be only slightly larger than the emitter temperature. At currents large enough for the plasma resistance to become noticeable this model ceases to apply because the plasma will no longer be equipotential. A good qualitative insight can be obtained by using Steenbeck's principle, according to which the potential profile and the electron temperature will adjust themselves in such a way as to make the total heat dissipation at given current a minimum. The heat dissipation per unit current is $V + 2kT/e$, the second term being the kinetic energy which the electrons give up to the collector, and the electron temperature T must be such as to make this a minimum. As by Spitzer's law the plasma resistance is proportional to $T^{-3/2}$, the electron temperature will increase with rising current, ultimately with the 2/5

Fig. 2. Potential diagram. At light loading (broken lines), the plasma has a uniform potential, at heavy loading (continuous lines), the effect of plasma resistance becomes noticeable

power of the current density. This is qualitatively illustrated in Fig. 3, where the base $4kT/e$ broadens with increasing current. Experimentally we have observed an increase of kT/e from 0·11 V. at small currents, to 0·25 V. (2,900° K.) at the largest densities investigated.

This is one of the effects of large currents. The second is a shift in the characteristic, owing to the gradient in the plasma. This, too, is illustrated in Fig. 3. At the point where $I = 0{\cdot}75\ I_{max.}$, which would correspond to $V = 0$ if the plasma were equipotential, the characteristic at higher current densities is shifted to the right by an amount V, which is the drop in the gas space. To obtain an idea of this drop note that Spitzer's law gives a plasma resistivity of the order:

$$\rho = 1{\cdot}0\ (T/1{,}000)^{-3/2} \text{ ohm. cm.}$$

At the low electron temperatures with which the thermionic converter operates this is quite appreciable. Even at $T = 2{,}900°$ K. it is still 0·2 ohm. cm. Thus, if we had a plane emitter faced by a plane collector at a distance of 1 cm., we should have at 4 amp./cm.^{2} a drop of 0·8 V., which is far too large

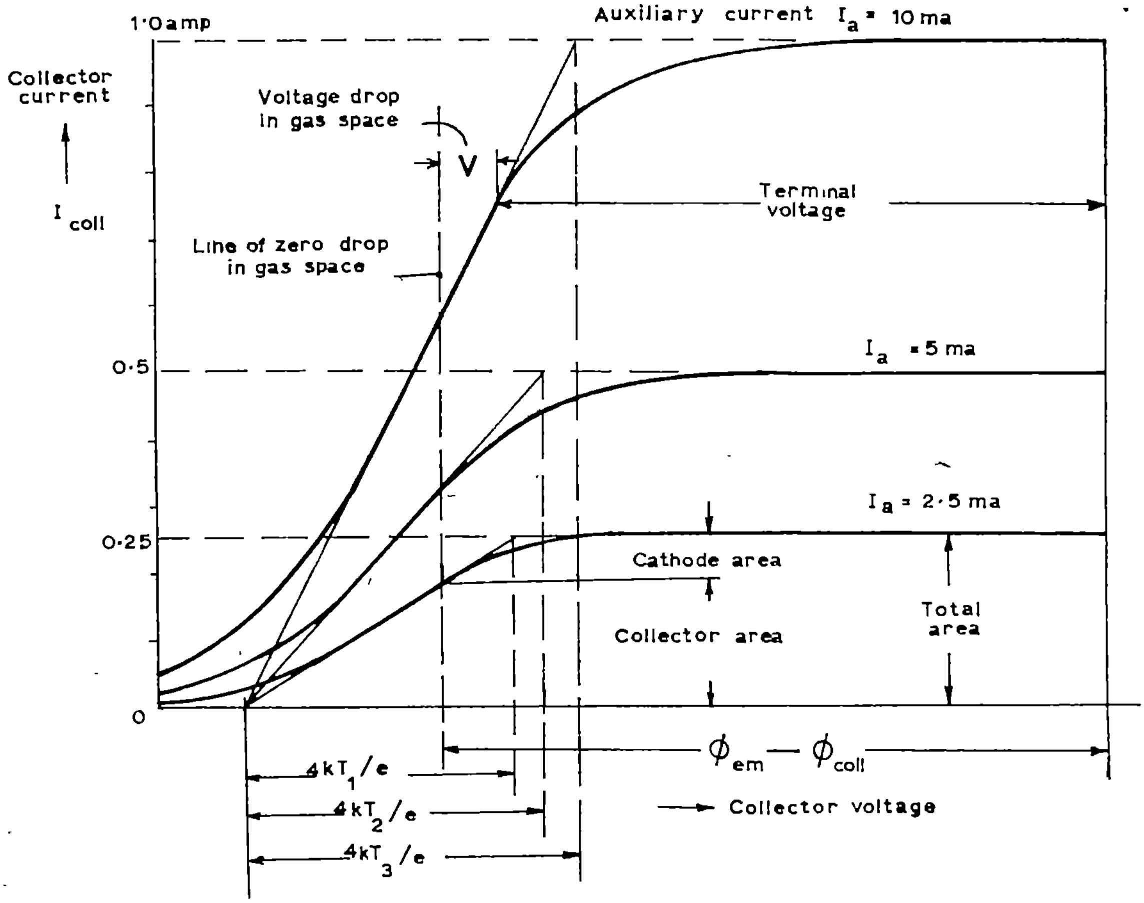

Fig. 3. Current-voltage characteristics, schematic

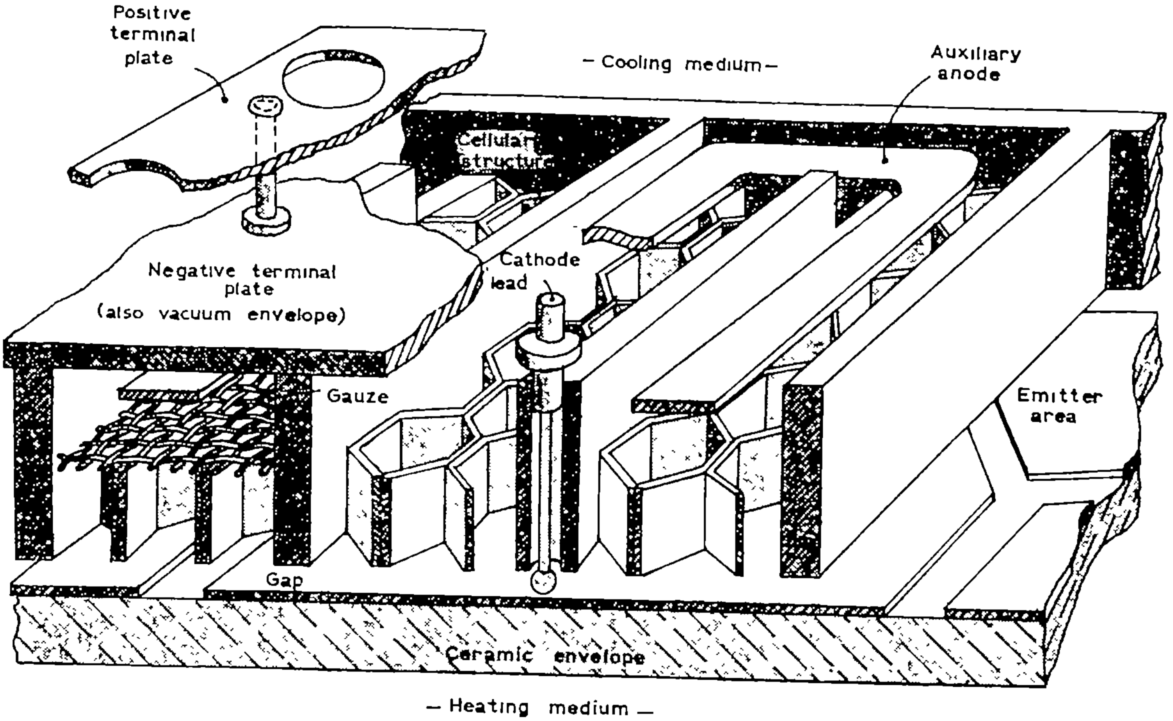

Fig 4. Thermionic generator element

to be tolerable. This has an important consequence for an economic design. It was shown previously that in order to reduce the voltage drop, the collector area must be large relative to the cathode area. It is seen now that in addition we must also reduce the absolute dimensions of the emitter-collector assembly.

Fig. 4 shows a design of a thermoelectric generator in which this is taken into account. The collector consists of a cellular metal structure, of a material with good heat conductance, interspersed with bars of sufficient cross-sections to conduct the heat without a large temperature-drop to a terminal plate, which is immersed in the coolant. The cells have small dimensions, say 3–5 mm., and they are within a small distance, say 1 mm. from the face of the emitter, so that the plasma resistance is that of a pair of parallel plates at about 2 mm. distance. This is sufficient for current densities of the order of 4 amp./cm.^{2}; for higher densities the dimensions ought to be further reduced. It is seen that the fineness of this 'microstructure' does not prevent the realization of large units.

A metal gauze is applied to the top of the cellular structure, separating the auxiliary discharge space from the main space. This second space contains a meandering auxiliary anode. It has been found that a single auxiliary discharge space is preferable to one broken up into smaller units, as it ensures that the discharge will spread over the whole surface of the gauze.

While most prime movers improve in efficiency when they are scaled up, large thermionic generators beyond a certain size suffer from a grave disadvantage. This is the self-magnetic field of the generated current, which tends to prevent the emission by returning the electrons to the emitter. One can reduce this somewhat by admitting the currents not at one point but evenly over the periphery of the device, but only up to a certain limit. As an example, let 25 gauss be the limit of the magnetic field parallel to the emitter surface which one can tolerate. Such a field is produced by 20 amp./cm. With a current density of 4 amp./cm.^{2} this limit is reached in a square of 20 × 20 cm., at a current of 1,600 amp. If one makes the unit larger the current will not increase, because the emission will be cut off beyond the critical square. Larger units must consist 'magnetically' of sub-critical units. One way of achieving this is shown in Fig. 4. The emitter area is divided into hexagonal sub-areas, each with its own cathode lead in the centre. If these are small enough the loss by magnetic fields can be made negligible. For example, if each sub-unit supplies 100 amp. and has an area of 25 cm.^{2}, the critical area around the lead in which the magnetic field is more than 25 gauss has a radius of 0·8 cm. and an area of 2 cm.^{2} only, that is, 92 per cent of the emitter area is utilized. An advantage of this design is that each cathode lead acts also as a mechanical support for the ceramic envelope against the atmospheric pressure. Moreover, one finds that if these leads are made, for example, of tungsten or molybdenum, of such thickness as to present the optimum compromise between ohmic drop and heat conduction, they will be flexible enough to follow the differential thermal expansion between the emitter and the collector structure. All cathode leads are connected with a positive terminal plate which is perforated and immersed in the coolant. Such units can be made in any size, and they need not be necessarily plane.

The efficiency of thermionic generators has been calculated by several authors, in particular by J. M. Houston[7]. It is

$$\eta = \frac{\varphi_{\text{em}} - \varphi_{\text{coll.}} - RI - (\text{drop in discharge}) - (\text{cost of ions in W./amp.})}{\varphi_{\text{em.}} + 2(k/e)T_{\text{em.}} + (\text{heat conduction/amp.}) + (\text{radiation/amp.})}$$

RI is the internal ohmic drop. The optimum compromise between this and heat conduction is usually at RI = 0·05–0·1 V. The conditions which favour a small voltage drop in the discharge and reduce it to 0·1–0·2 V. or less have been already discussed, and it has been mentioned at the beginning that the cost of ions can be made as low as 0·05–0·1 V. in the present device. The most important parameters for good efficiency are therefore the work functions $\varphi_{em.}$ and φ_{coll} and the radiation per ampere emission. The heat conduction through argon at about 2 mm. pressure plays a small part in the losses. The work function of the collector must be evidently made as small as possible. It can be reasonably expected that it will be possible to reduce it to 1 V. This leaves us with finding a suitable compromise between the emitter work function and the radiation loss per amp. current. The best compromise depends on the emitter temperature. If this is given, one has the choice between a larger $\varphi_{em.}$ giving a higher terminal voltage but smaller currents and thereby larger radiation loss per ampere, or a smaller $\varphi_{em.}$ with smaller radiation losses. At emitter temperatures of 1,500°–1,800° C. the choice is largely in the region $\varphi_{em.}$ = 2–3 V., and working out examples with existing emitter materials one finds that the advantage is on the side of the lower work functions. These give not only better efficiencies but also higher power densities, that is, better utilization of space. With present cathode materials one can contemplate efficiencies of the order of 20–30 per cent and power densities of the order of 4–6 kW./sq. ft.

It is a unique advantage of the new device that it allows the direct generation of alternating current. The device becomes at once non-conducting if the auxiliary discharge is extinguished, and can be made conducting in a fraction of a millisecond by re-striking it. Thus, if one takes two of these devices and connects them in push–pull over a transformer as output, so that they will send currents into the transformer alternatingly, one obtains alternating power. One can supply this to an a.c. network by deriving the small auxiliary power from the mains in synchronism with it. The efficiency in a.c. operation is somewhat smaller than with d.c. because heat conduction and radiation go on also during the non-operative half-cycle, but the reduction in efficiency (say from 30 to 22 per cent) might well be outweighed by the gain in the cost of the plant.

Though the investigations of the gas discharge in the new thermionic device are not yet closed, these phenomena are now sufficiently understood to form the basis for the design of practical generators—given suitable materials. Further research must be directed towards the three problems in material technology presented by this or any other thermionic converter. The first is a cathode material with 2–2·5-V. work function, with small radiation emissivity, capable of supplying 4 amp./cm.[2] or more at temperatures in the region of 1,200°–1,800° C. The second is a suitable collector with high reflectivity and low work function. In a self-contained generator in which the coolant temperature is, say, 100° C., this ought to be about 1 V. In a generator used as a 'topper' for a steam turbine, with the coolant at 5–600° C., it can be 1·5–1·8 V., and there exists a fairly wide range of suitable materials. Such a converter would amount to a boiler which turns a part of the fuel energy directly into electric power, the rest into steam.

The third problem, probably the most difficult, is that of a ceramic envelope impervious at 14–1,800° C., capable of operating for long times when exposed to flame gases and with a high thermal shock resistance. This last problem would not arise in one line of possible applications, namely, as a converter in an atomic reactor in which the nuclear fuel could be included in the envelope. This application, however, will not mature until it is proved that fuel elements can operate at such high temperature, and do not contaminate the emitter, the collector and the gas with fission products. A small amount of gas contamination, as well as some measure of gas transmission in the ceramic envelope, can be dealt with by titanium pumps or the like, which eliminate chemically active contaminants, but not argon or other inert gases.

Provided that these problems can be solved satisfactorily, combining a low cost with a long life, there is a wide field of potential applications for thermionic generators, in supplying d.c. power for electrochemical plants, for traction, for small self-contained generator units, and for improving the efficiency of large steam or nuclear power plants.

My thanks are due to Mr. H. A. Fatmi, who has carried out the experimental work, and to the National Research Development Corporation, which provided the financial support.

THE MARITIME UPLANDS OF BRITAIN: INVENTORY AND PROSPECT

By JAMES A. TAYLOR

Department of Geography and Anthropology, University College of Wales, Aberystwyth

THE alleged equability of British climate is a notion derived not only from a traditional consideration of exclusively mean meteorological data but also from the fact that the vast majority of the major synoptic meteorological stations of Britain are situated at low elevations (see Fig. 1). It is well known that weather, climate and ecological potential deteriorate with increasing altitude in the British Isles, but the remarkably rapid rate of deterioration, even for a maritime climate, is much less publicized. If, for idealized maritime and continental sites (Fig. 2), horizontal lines A (low-level) and B (high-level) for the former, and lines A' (comparable low-level) and B' (comparable high-level) represent growth thresholds (for example, 42° F.) crossed upwards in spring and downwards in autumn

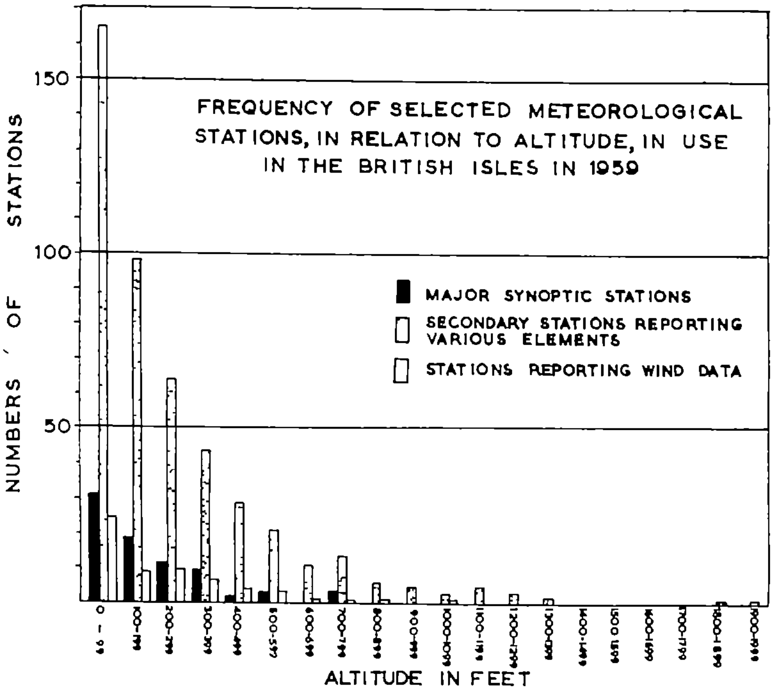

Fig. 1

by the mean monthly temperature curves, then the vertically shaded and stippled areas represent the relative amounts of growth potential at each site and elevation. Clearly, the maritime site, despite its earlier and longer season, has a lower growth potential, which is reduced rapidly with elevation. The continental site, however, despite its later and shorter season, has a greater growth potential which is reduced much less rapidly with elevation. It follows that agricultural limits, tree-lines, snow-lines, etc., occur at much lower elevations at maritime, compared with continental, sites.

This sharp ecological gradient[1] is the expression of decreasing temperatures, especially maximum temperatures, and of increasing rainfall, derived more from the elevation and modification of frontal structures than the simple rise of moist air streams. Increasing cloud cover and persistence, relatively low-cloud bases, high humidities and the liability to mist or fog accompany the increasing rainfall. Complementarily, evaporation (when it is possible) and sunshine amounts are reduced to a minimum. Frost incidence, snow-fall, snow-cover[2] and wind-speed[3], with few exceptions, also increase with altitude. All these trends imply a progressive, exceptional rate of deterioration of meteorological and ecological conditions with altitude in Britain.

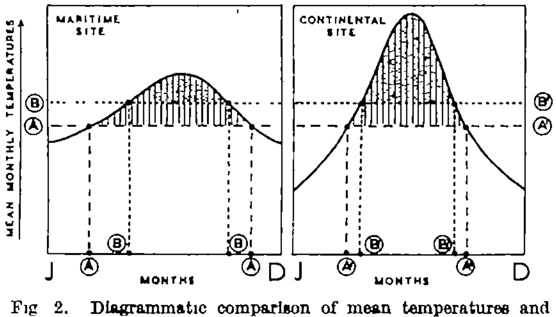

Fig 2. Diagrammatic comparison of mean temperatures and growing season at maritime and continental sites

The techniques of pollen analysis and carbon-14 dating have enabled a reconstruction of the vegetation chronology since the end of the last major glaciation (about 12000 B.C.). Tundra was eventually succeeded first by birch and pine forests and then by mixed, deciduous oak woodland which, by the post-glacial climatic optimum (6000–2000 B.C.), attained elevations substantially higher than the 2,000-ft. contour. During the early Mesolithic (8000–6000 B.C.), upland Britain was extensively covered with birches and pines under a relatively dry, continental 'Boreal' climate. From the late Mesolithic (5000–2800 B.C.) through to the Neolithic and the end of the Bronze Age (about 500 B.C.), thick, deciduous woodland containing much oak and alder dominated at first under a warmer, oceanic, 'Atlantic' climate from about 5000 B.C. to about 3000 B.C., and later under the drier régime of the 'Sub-Boreal' phase from about 3000 B.C. to about 500 B.C. Afterwards, the 'Sub-Atlantic' phase (about 500 B.C. *et seq.*) witnessed a resumption of a moister climate and progressively slow, then rapid, deforestation of upland Britain by man, and the creation of the moorland landscapes we know to-day.

Some of the more striking features of the 8,000 years of the post-glacial period are embodied in contemporary soil profiles in upland Britain. The deciduous forest climax was longer and more potent than the preceding birch and pine forests, and promoted the development of deep brown earths. The qualities of colour and texture in the *B* horizons of many contemporary hill soils at present under an incongruous grass vegetation may be attributed to this period. The thick mantle of hill peat developed on typically flattish or gently sloping sites accumulated in particular during the oceanic 'Atlantic' phases. On the other hand, the contemporary semi-natural moorland grasses have formed dense, matted root layers, forming the familiar 'organic-top' of many hill soils, below which a bleached A_1 horizon, greyish in colour, is characteristic. The local development of iron pans or organic pans at the top of the *B* horizons may create impedance within the profile, as evidenced in the mottling of the lower section of the A_1 horizon. These features are expressed in the peaty-gley-podzol which is the most common soil in upland Britain. They are the creation of past vegetations and climates as well as contemporary vegetation and climate, and of past, as well as present, usages by man and his grazing animals.

It is surprising that man's continuous, if extensive, use of the hills in Britain has not facilitated more intensive inquiry into the hill environment itself. The upland soils have been least modified by agriculture and could provide more direct evidence of post-glacial pedogenic processes than their intensively cultivated lowland counterparts. Yet the latter take precedence over the former in the programme of the Soil Survey. Again, the semi-natural upland vegetation is regarded as something to be improved and 'forced' for grazing purposes—rather something which, in fact, has been degraded by grazing. Detailed vegetation maps of the uplands of Britain scarcely exist. The upland climates of Britain, except for individual short-period investigations, remain taken for granted and often incompletely appreciated. The relatively low contemporary economic value of the uplands of Britain has been a major factor in this neglect. Once areas of pioneer colonization by primitive man, these uplands have now become depopulated and devalued by modern man. The agricultural lowlands and the coalfields have claimed priority in geological and pedological surveys[4]. The popular comment, "all our vegetation has gone" has perpetuated the almost peculiarly British notion that we live in a conquered environment virtually emancipated from the extremes of Nature. In the hill areas nothing could be further from the truth. Economists to-day repeatedly insist that the hills should be left to water conservation, afforestation, national parks and nature reserves. Hill soils and hill climates have been ecological proof of this doctrine for thousands of years. However, the relegation of sheep-farming and promotion of water conservation and afforestation requires careful and comprehensive planning, which should consider ecological, pedological and sociological argument, in addition to the purely economic considerations.

Cattle depopulation and the gradual disappearance of older sheep from upland Britain have caused a decline in intensity of grazing in recent decades. Consequent regeneration, especially of bracken, has proceeded at locally alarming rates. Bracken is apt to colonize the deeper, non-impeded brown earths which are normally the most productive and versatile soils on the slopes ; areal loss is thus coupled with loss of good land. Much Welsh *ffriddoedd* has been transformed into bracken fields dotted extensively with scrub oak, hawthorn and dwarf gorse. The monopolistic, selective grazing by sheep has allowed species such as *Nardus* and *Vaccinium* to dominate many associations at one time richer, for example, in *Molinia* and *Agrostis*. Heather monocultures (for example, in parts of the Scottish Highlands and on the Llandegla Moors in north-east Wales) induce relatively strong soil-podzolization and confine land use to extensive sheep grazing, usually by Scottish blackface.

The dairying revolution of the period *circa* 1933–52 is still registering in remote parts of the uplands of Britain, affording modern evidence of the traditional delay in cultural response which has characterized the Highland Zone of Britain since the earliest times. Some mid-altitude farms have recently introduced milk production, provided they were located within, or within reach of, the catchment of a milk lorry. Many what may be termed 'natural rearing farms' have been modified in this fashion in response to the temporary and, in many ways, excessive economic provocation embodied in the attractive marketing and price facilities and the regular income offered by the Milk Marketing Board. At the same time, sheep farmers face the annual problem of the high cost of wintering their flocks on lowland farms. The comparatively short-term economic and political arguments which initiate these trends and problems should always be qualified by the excessively sharp decrease in flexibility and adaptability of farming systems, and of farms with large proportion of 'hill', with increasing altitude in the maritime uplands. Also, the law of systematic and regular integration between hill farm and lowland farm is herein revealed and is inescapable.

Relatively recent allocations of hill land have been made to the Forestry Commission, to water and electricity authorities, to the National Parks Commission, the National Trust and the Nature Conservancy, to the Army and to the British Atomic Energy Authority.

To what extent the introduction of conifers (for example, since 1927 in Dovey Forest) on partially podzolized soils has induced further podzolization is debatable. Preliminary evidence[5] indicates that little, if any, perceptible degradation has taken place, in particular in Wales, where parent materials in general do not possess an adequate combination of extreme porosity and acidity, as for example occurs in the Barton Sands of the New Forest, where a period of only twenty-five years under conifers has been enough to create advanced podzolization[6]. Afforestation, on the other hand, has helped to check rural depopulation and has provided good, new access roads for many hill farms.

The economic priority claimed by water and electricity authorities in the creation of reservoirs and impounding of water must be assessed against what often amounts to the effective elimination of the antecedent forms of land usage. Planted trees may share the slope with sheep, trees and sheep may occupy land within a national park, but a flooded valley must lose not only its trees and its sheep but also its land as a whole, good, bad or indifferent, and its settlements, people and history. The valley, as it were, dies. But a new lake, a new landscape is created, and miles away a new industry expands and flourishes.

Extensive sections of hill country in Britain have been declared as national parks and provide extended scope for tourism, the industry which to-day can claim one of the largest individual incomes in the country. Tourism, together with water storage, represents potentially one of the most profitable uses which can be made of the uplands of Britain, provided modernized accommodation and hostelries of the right calibre can attract an adequate range of tourists. This will require continual improvements in communications, especially by road.

More limited hill areas have been taken by the Nature Conservancy and the National Trust, and afford opportunities for studying the relation of plant regeneration to soil, slope and climate. Evidence derived from such an investigation will confirm the ecological law that, with increasing altitude in Britain, it becomes progressively—and soon remarkably—less profitable to create artificial soil conditions to introduce lowland species of plants or plants bred specifically to cope with more rigorous environments. Whatever success is achieved on a re-seeded hill, grazing is notoriously short-lived and uneconomical.

The availability of large areas of unpopulated hill has among other factors favoured the creation of army training camps and, very recently (1960–61), the establishment of nuclear power stations, such as that at Trawsfynydd in Merionethshire.

Hill farming leans on Government subsidies. Forestry represents a long-term Government investment. Forestry, in the long run, is relatively more profitable per acre and employs more men per acre[7] than hill-farming which, for the most part, retains the better land on the lower slopes and plateaux and valley bottoms, permitting plantation on the higher, or more exposed, or more steeply sloping, ground. It is reasonable to argue that, given equal status in land allocation, forestry would be even more profitable than hill-farming and on lower ground even more profitable still. But sheep farms are indigenous, as it were, to the hills; the plantations are intrusive. Forestry can exploit the more remote hill land more effectively, but at the cost of a longer journey-to-work. The sheep farm (except for certain types of fragmented holding), is a more self-contained labour unit with traditional, external contacts for marketing and social excursions. Rearrangement and amalgamation of holdings might be advocated to promote, rather than reduce, these contacts. New villages created *ab initio* by the Forestry Commission pass through a very difficult formative period until the second generation, born in the village, becomes adult. It is wise to extend old villages where a traditional community spirit already exists. Under-grazing by sheep has allowed extensive regeneration and loss of hill grazings, and soils undisturbed under matted grass (and derived organic top-layers) for many years become badly aerated and deficient in moisture in dry spells. Re-introduction of store cattle on the hills to graze with the sheep would help to reduce degeneration of grazings. In contrast, preliminary treatments for tree-planting often include deep ploughing, especially when drainage is poor and, although catchments may become temporarily flooded by the improved drainage, the mechanical disturbance and overturning of the soil breaks up the root mat, improves aeration and brings relatively richer *B*-horizon material to the surface. On steep slopes, however, there is a danger that erosion might occur.

The implication of the foregoing paragraphs is that whereas forestry must in Britain claim economic priority over hill-farming virtually to the extent of being permitted access to some of the better land, the deep-rooted traditions of the countryside and its settlement pattern remain centred on its sheep farms and associated hamlets. Also, the implication is that the two can be usefully integrated rather than being allowed to compete; this point will be developed later.

Clearly, the future expansion of industry in Britain and the maintenance of a national economy based on adequate exports will demand more extensive and more efficient harnessing of the water resources of the country, in particular in the Highland zone. Thus, water storage both for industry and for power development must claim the highest priority in the planning of upland land use. On the whole, the afforestation of catchments of reservoirs might be favoured, causing further shrinkage of areas devoted to hill-farming. Sheep are tolerated more on the catchments than cattle as a rule; thus the mixed grazing advocated above on ecological grounds is not always practicable. The relatively small areas taken by the Nature Conservancy, the National Trust, the Army and the Atomic Energy Authority are fully justified in terms of urgent national requirements, and the functions of those organizations. The larger national parks are equally justified on grounds of amenity and tourism. It should be asserted, however, that sites of supreme ecological interest or natural beauty should, so far as possible, not be adopted either for military training or for the establishment of nuclear power stations.

In summary, the general order of priority of land use in the uplands of Britain, according to contemporary economic trends, would be as follows: (1) water conservation for industry and for power; (2) afforestation, including the establishment of shelter belts; (3) stock-farming, including store cattle as well as sheep on reorganized amalgamated holdings.

Within this broad framework of priorities, the local priorities concerning (*a*) tourism, both coastal and rural, winter and summer; (*b*) nuclear power stations; (*c*) military and conservation allocations seem justifiable, provided ecological and æsthetic arguments are satisfied.

The creation of a reservoir eliminates all other forms of land use from the site. Cattle-grazing is not encouraged on the catchment of the reservoir, where afforestation is favoured rather than sheep grazing. Forestry, claiming slight relative economic priority, may in the future deserve better hill land at the expense of the adjacent sheep farms, and even some lower ground at the expense of lowland farms. Afforestation blocks may reduce the internal mobility of a sheep farm. The forests may have been sited long distances from existing settlements, where there is competition for a limited and ageing labour force. New settlements vie with old settlements for people and social and religious privileges. External (for example, non-Welsh) forces in the form of new jobs and new workers compete with local tendencies to conservatism and conventionality. How can a declining population maintain cultural integrity and assimilate incoming cultural influences without suffering dilution? How can old and new elements in the labour force continue to tolerate life in remote hill areas, when for many individuals it probably hangs at this moment by the slender penetrating thread of the television screen? How long will it take for the influence of the progressive emancipation of generations of women and mothers to encompass all rural areas? How long will parents and local authorities tolerate an educational system which permits variety in local opportunity for children at the age of 11+ years and demands the steady annihilation of the country schools within the devouring, centralizing orbit of large, new, cumbersome secondary schools to which rural children are 'exported' and 'imported' daily over many miles? How can this picture of all-round competition and collective decline be reconciled?

Reconciliation must lie in integration, which necessitates some degree of planning. The location of water storage schemes should be arranged so as to create a minimum of dislocation of existing settlement and economy. The Forestry Commission should be encouraged to continue to plant above the commercial tree-line for shelter purposes on sheep farms and allowed to experiment on lower ground to ascertain possible increases in yield. Sheep farmers should be educated to accept some degree of reorganization and amalgamation of holdings as the price to pay for greater economic and social security. The re-introduction of store cattle would give more flexibility to the farming system. The occupiers of the smaller holdings should be encouraged to take part-time jobs in the Forestry Commission which should be made available in its programmes of future expansion. For time immemorial the earlier inhabitants of the hills combined several tasks, for example, domestic craft, mining, sheep farming, cattle farming, and the basis of their success was co-operation, especially during the vital summer months when the mountain pastures were systematically grazed. These ancient laws of job combination and co-operation probably still apply even in the different economic world of to-day. New settlements should be representative of all the labour force and not confined to one type of worker, for example, forestry employees. Moreover, they should be attached to, or be within easy reach of, existing settlements and amenities. Improvement of communications, achieved by the Forestry Commission, for example, should go hand in hand with other forms of planning land use, making the economy more efficient and attracting a bigger and more versatile tourist trade.

These anticipated plans imply change in one form or another. The view that rural cultures (for example, Welsh culture) should not tolerate contamination should be weighed against the inevitability of the economic decay that must accompany their continued isolation.

This commentary owes much to a symposium on "Hill Climates and Land Usage, with special reference to the Highland Zone of Britain", convened by the author in Aberystwyth in March 1960. A memorandum including ten papers was compiled, based on the discussion, and circulated as *Mem.* No. 3, Aberystwyth. Grateful acknowledgment is also made to Prof. Gordon Manley for many valuable criticisms.

NEWS and VIEWS

The Royal Society of Edinburgh : Awards

THE following awards have been made: *Makdougall–Brisbane Prize* (1958–60), to Mr. Albert G. Long, Duns, Berwickshire, for several papers on palæobotany published in the *Transactions* of the Society during the period of the award. *Dr. W. S. Bruce Memorial Prize* (1960), to Mr. J. MacDowall, Meteorological Office, London, for his work in the fields of Antarctic meteorology and geomagnetism and as leader of the Royal Society of London Expedition to Halley Bay, 1958 (this Award is made jointly with the Royal Physical Society and the Royal Scottish Geographical Society). *Bruce–Preller Lecture* (1961): Dr. V. A. Eyles, formerly H.M. Geological Survey, London and Edinburgh, has been invited to deliver the Bruce–Preller Lecture, 1961, at the ordinary meeting of the Society on June 5.

New Fellows

THE following have been elected Fellows of the Royal Society of Edinburgh: Dr. F. Alexander, reader in veterinary pharmacology, University of Edinburgh; M. Campbell, secretary, Department of Agriculture and Fisheries for Scotland; Dr. A. J. O. Cruickshank, reader in electrical engineering, University of St. Andrews; Prof. R. B. Dingle, professor of theoretical physics, St. Salvator's College, University of St. Andrews; Dr. P. S. Farago, senior lecturer in natural philosophy, University of Edinburgh; Dr. P. B. Fellgett, principal scientific officer, Royal Observatory, Edinburgh; K. B. Fraser, senior lecturer in botany, University of Aberdeen; Prof. A. Haddow, professor of experimental pathology in the University of London, and director of the Chester Beatty Research Institute, London; W. T. Harry, lecturer in geology, University of St. Andrews; Prof. A. W. Hendry, professor of building science, University of Liverpool; Prof. J. S. S. Inglis, professor of animal husbandry and preventive medicine, University of Glasgow; Dr. H. Lister, lecturer in polar studies, University of Durham, Department of Geography, King's College, Newcastle upon Tyne; D. Lowe, horticulturist, Elvingston, Gladsmuir, East Lothian; Dr. R. C. Mackenzie, head of the Department of Pedology, Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen; B. Noble, senior lecturer in mathematics, Royal College of Science and Technology, Glasgow; B. B. Parrish, Department of Agriculture and Fisheries for Scotland, Marine Laboratory, Aberdeen; Prof. P. L. Pauson, Freeland professor of chemistry, Royal College of Science and Technology, Glasgow; Dr. R. J. T. Pennington, research fellow to the Neurological Unit, Medical School, King's College, Newcastle upon Tyne; Dr. B. B. Rae, assistant to the Director of Fisheries Research, Scotland, Department of Agriculture and Fisheries for Scotland, Marine Laboratory, Aberdeen; Prof. J. R. Raeburn, Strathcona-Fordyce professor of agriculture in the University of Aberdeen; R. M. Sillitto, lecturer in natural philosophy, University of Edinburgh; Dr. F. Smithies, lecturer in mathematics, University of Cambridge; Dr. D. W. N. Stibbs, Napier professor of astronomy in the University of St. Andrews, and director of the Observatory; Dr. A. B. Taylor, Registrar General for Scotland.

Physics at Manchester : Prof. E. B. Paul

DR. E. B. PAUL, who has been appointed to a chair in the Department of Physics of the University of Manchester, was educated at Mallorytown and Brockville Schools and at Queen's University, Kingston, Ontario. From 1942 until 1946 he held an appointment with the National Research Council of Canada at Ottawa and took part in the work on nuclear reactions sponsored by that body in connexion with the development of the Chalk River Laboratories. During 1946–48 Paul studied at Cambridge, where he worked with the 1-MV. high-tension generator of the Cavendish Laboratory and took his Ph.D. degree. He then returned to the Physics Division of the Chalk River Laboratories and undertook an extensive investigation of neutron activation cross-sections which has been widely quoted. Following this, he turned his attention to proton-induced reactions and was for the next few years a leading member of a group which has published many papers on resonant processes in the light nuclei. The high standard of this work both in experimental technique and in theoretical analysis has contributed greatly to the international reputation of the Chalk River Laboratories. In 1955 Paul was appointed to the Atomic Energy Research Establishment, Harwell, where he is now in charge of nuclear research using electrostatic generators, and is deputy head of the Nuclear Physics Division. Paul is well known for his interest in nuclear structure; he was the first to point out that the collective model could give an excellent account of the properties of levels of light nuclei. His ability in interpretation and his wide experience of high-tension work will be of great service to Manchester, where a vigorous programme of research in low-energy nuclear physics is already in being.

Prof. H. E. Hall

DR. H. E. HALL, who has also been appointed to a chair of physics at Manchester, is only thirty-two. He was educated at Latymer Upper School and Emmanuel College, Cambridge. He went to the Royal Society Mond Laboratory in 1952 and quickly made his mark as an exceptionally skilled experimenter who was equally at home in the construction of delicate equipment and in the mathematical analysis of his results. He carried out a variety of researches on liquid helium which have led to a significant elucidation of our understanding of its properties. Probably the most important contribution to this understanding was an elegant experiment, in collaboration with Dr. W. F. Vinen, in which they showed that second sound was attenuated when propagated in rotating liquid helium II; this demonstrated very directly the existence of vortex lines. In 1958 he was appointed lecturer in the University of Manchester, and has contributed to the development there of a vigorous low-temperature group; he has also expanded his interests and taken up some interesting problems concerned with the Mössbauer effect.

British Scientific Attaché in Paris: Mr. R. V. Melville

MR. RICHARD MELVILLE, of the Department of Scientific and Industrial Research, has been appointed scientific attaché to the British Embassy in Paris. He will advise the British Ambassador on scientific matters and report on French scientific and technical development in the civil field. Mr. Melville, who is forty-seven, will hold the rank of senior principal scientific officer. He has been with the Department of Scientific and Industrial Research since joining the Geological Survey and Museum in 1938. He has recently been on secondment to the International Commission on Zoological Nomenclature as assistant secretary, which has brought him into close contact with French scientists. Mr. Melville, who is French-speaking, has also taken part in scientific expeditions in France and French North Africa. Educated at Wellington College and in the United States, he graduated at the University of Reading in 1936, obtained a special honours degree in geology the following year and obtained his M.Sc. in 1941.

Prof. Peter Pringsheim

PROF. PETER PRINGSHEIM, who will be eighty years of age on March 19, was born in Munich, son of a distinguished mathematician, his mother being formerly an actress. He grew up in a home of culture, music and of literary interest. His sister married Thomas Mann. Prof. Pringsheim spent some time in Cambridge with J. J. Thomson, but then joined Rubens in 1909. His career was profoundly affected by the two World Wars. In 1914 he was attending the British Association meeting in Australia when war was declared and he was interned for its duration. During his enforced leisure he wrote the text of his monograph on fluorescence and phosphorescence which, together with his work in the field of fluorescence of vapours, established him as an authority. Soon after his return from internment he was appointed professor in the University of Berlin, where he remained until dismissed in 1933 because of his partly Jewish descent. He moved to Brussels with his Belgian-born wife; but in 1940 was overtaken by another World War, being arrested and taken to a camp in France. Fortunately, his American friends secured his release and he was able to reach the United States to work first in California and later in the Argonne National Laboratory, although he was not reunited with his wife until 1946. In 1954 he retired to Antwerp but maintained his interest in luminescence.

In the early 'twenties Prof. Pringsheim extended his interest in luminescence to the fluorescence of organic molecules in condensed systems. He contributed to the *Handbuch der Physik* in his field. The years of the Second World War led to a revision of his book, and in 1946 a new, monumental text was ready, perhaps the last possible attempt anyone could make to provide a comprehensive review of luminescence in the gaseous, liquid and solid states. Although he regretted that so much of the war-time advances in luminescence was released after the publication of his book, Pringsheim's text still stands as a landmark in luminescence, with its bibliography only a little short of two thousand references. He completed his own research interests by a post-war incursion into the problems of luminescence and colour centres in the alkali halides, reviving a previous interest in the fluorescence of heavy metal ions complexes in solution. He is one of the few people who has attended almost all the major conferences in his subject and it was a pleasure to see him, even in retirement, participating in the Paris Conference of 1956.

Effects of Radioactivity in the Sea

RESEARCH on the effects of radioactivity in the sea is to be undertaken by the International Atomic Energy Agency under an agreement recently concluded between the Agency, the Government of Monaco and the Oceanographic Institute in Monaco. The research, which will be conducted at the Scientific Centre of the Government of Monaco, is related to the problem of possible pollution of the sea through the deposition of radioactive materials. It is aimed at studying: (*a*) the movement of water and marine organisms and the deposition of organic and inorganic matter; (*b*) the distribution in marine organisms of radioactive materials already existing or that may be introduced into various locations; (*c*) the effects on marine life of radioactive materials at various concentration-levels. The programme has been approved by the Agency's Scientific Advisory Committee, which is composed of seven leading scientists from different countries. The research, which will start soon, is planned to extend for three years. The laboratory and working facilities of the Scientific Centre in the Oceanographic Museum and a wide variety of electronic and monitoring equipment will be made available by Monaco. The Oceanographic Institute will put at the disposal of the project a number of valuable facilities, including marine biology laboratories, oceanographic vessels and some specialized fishing equipment. Certain other facilities, including the 360-ton oceanographic ship *Calypso*, may also be available through the Institute. The Monaco Government will contribute 200,000 French new francs for each year of the research project. The Agency will appoint a chief scientist to be in charge of the research and provide other personnel as well as specialized equipment and technical supplies. Agency fellowships will be awarded for training in connexion with the research project.

Co-operative Nuclear Research

In a written answer to a question in the House of Commons on March 7 as to the projects in which the United Kingdom is participating under the auspices of the European Nuclear Energy Agency, Mr. D. Freeth, the Parliamentary Secretary for Science, named the *Dragon* project at Winfrith Heath for the development of the high-temperature gas-cooled reactor and the Halden project in Norway for the development of a boiling-water reactor. The United Kingdom is also co-operating fully in the general work of the Agency through membership of specialist panels, committees and symposia. The *Dragon* project is managed by an international board, the United Kingdom representatives on which are appointed by the Atomic Energy Authority. According to the report for the year ended March 31, 1960, a start has been made on the construction of the experimental reactor, and Mr. Freeth understood that satisfactory progress is continuing. In reply to other questions, Mr. Freeth said that between 35 and 40 graduate physicists, drawn from physics departments in four universities, are making regular use of the facilities at the Rutherford Laboratory at the National Institute for Research in Nuclear Science, Harwell, and teams from two more physics departments would shortly be doing so. Present estimates indicate that the annual output of qualified scientists and technologists in Britain should reach 20,000 by about 1964, or after only eight years, instead of the 10–15 years recommended by the Scientific Man-power Committee of the Advisory Council on Scientific Policy.

Toxic Chemicals and Wild Life

In reply to a question in the House of Lords on March 9, the Joint Parliamentary Secretary to the Ministry of Agriculture, Fisheries and Food, Earl Waldegrave, said the attention of the Government had been directed to the report issued on February 22 by the joint committee of the British Trust for Ornithology and the Royal Society for the Protection of Birds on the effect upon birds and mammals of toxic chemicals used in agriculture. Comprehensive measures for dealing with this problem were agreed at a meeting last December convened by the Department, at which representatives of these two bodies were present, as well as delegates from the Council of Nature, the National Farmers' Union and the Association of British Manufacturers of Agricultural Chemicals. The measures agreed included a survey by the Ministry's pests officers of reported cases of unusual deaths among birds, foxes and badgers, and the results of the survey are to be reviewed with the interested organizations after this spring. The need for further research into the effects of the use of toxic chemicals in agriculture is being examined by a research study group appointed last year. While the Minister thought that these new arrangements would provide valuable evidence on which to base any further action which may seem necessary, he wished it to be widely known that the Government would welcome full information from naturalists or other interested persons about suspected poisoning of birds or mammals by toxic chemicals.

This reply did not entirely satisfy Viscount Elibank, Lord Hurcomb, Lord Shackleton and others, and points were pressed about the omission of any reference to possible dangers to wild life from the Ministry's 1961 list of approved chemicals, the desirability of independent inquiry and the effectiveness of co-ordination between the Ministry, the Agricultural Research Council and the Nature Conservancy. Lord Waldegrave said that he understood that an appendix to the notification scheme dealing with wild life is under discussion with the Nature Conservancy and other bodies, and he undertook to consider embodying a statement in the list itself in due course. Some concern was expressed as to whether sufficient research is proceeding, and Lord Hailsham, Minister for Science, agreed that co-operation could be improved and promised to consider issuing a statement as to the extent of research in progress. He did not, however, enter on the question of relations or co-ordination between the Agricultural Research Council and the Nature Conservancy, on which he was challenged by Lord Shackleton.

National Research Development Corporation of India

The sixth annual report and statement of accounts of the National Research Development Corporation of India covers the year ended March 31, 1960, in which fifty inventions were reported for development by eleven research institutions and individuals, bringing the total to 553, of which 397 are effectively in hand (Pp. 25. New Delhi : National Research Development Corporation of India, 1960). Thirty licences were negotiated and five processes went into production, making the total licensed and in production 37, with 51 licensed, but not yet in production. A new project on lightning arrestors has been sanctioned at the Indian Institute of Science, Bangalore, at an estimated cost of Rs. 1.60 lakhs. Installation of the pilot plant for phthalic anhydride at the Central Fuel Research Institute, Jealgora, is in hand and that for the de-ionization of cane juice at the National Sugar Institute, Kampur, has been installed. Pilot plant for white cement from felspar and a semi-commercial fluidized bed unit for textiles processing are being created.

New West Durham Borehole

At a recent meeting of the Geological Society at Burlington House, Piccadilly, Prof. K. C. Dunham, of the University of Durham, announced the results of a borehole that is being made at Rookhope in West Durham, and financed by the Department of Scientific and Industrial Research. Prof. Dunham, who has carried out extensive work on the metalliferous deposits of the Pennines, has for many years held the view that these continue to greater depths than have so far been exploited, and that they are related to an underlying granite mass. Support for the latter view has come from measurements of the variations in the gravity field by Dr. M. H. P. Bott, also at Durham. The borehole has now penetrated the 'hidden' granite 1,280 ft. below the surface, and has thus indicated that valuable minerals continue to three times the depth of local mining. The source of the minerals, nevertheless, lies at still greater depth, and the borehole is being continued.

Journal of Theoretical Biology

The first question one asks about this, as indeed about any, new journal is why is it necessary ? As the chief editor says in his preface, "it has frequently been difficult for an author to find an acceptable medium for theoretical papers" as contrasted with experimental ones ; and in this one must regretfully concur. Nevertheless, a journal devoted to theoretical papers over the whole of biology must, one would have thought, have had a unifying objective beyond that of providing an asylum for homeless brain-children. There is excitement abroad in biology to-day, just as there is excitement in cosmology, in nuclear physics, in theoretical chemistry ; and it is this excitement which, one feels, a journal of theoretical biology should catch, encourage and sustain. In the first issue there are several mathematical and physical papers which would leave the general biologist rather cold, a philosophical paper and an ecological paper which have little in them to excite the mathematician. There are, however, several papers of the kind one has in mind, dealing with the organization of cellular processes, one of which, by Dr. A. Szent-Györgyi, as might be expected from this author, being especially thought-provoking (*Journal of Theoretical Biology*, 1, No. 1. Subscription rates : (*A*) institutional subscribers, 121*s*. 6*d*. or 17 dollars ; (*B*) subscribers certifying that issues will be for personal use only, 86*s*. or 12 dollars. London and New York : Academic Press, Inc., 1961).

Kybernetik

We had occasion recently to take note of a new Russian journal which is being translated into English in Britain, concerned with cybernetics (*Nature*, 189, 795 ; 1961) ; our attention has now been directed to another journal, of similar scope, published in Germany, but edited by an international board. This is *Kybernetik*, published by Springer-Verlag of Berlin, and which is edited by a small group of people prominent in the field from Germany, Britain, the United States, Austria, France and the Netherlands. As with the Russian journal, the subject-matter in this relates to the transmission and processing of information and to automatic control processes, both as regards theoretical development within engineering and applications to models of biological functions. *Kybernetik* aims at cultivating experimental and theoretical work within the fields of information theory, control and automata theory, sensory processes and physiology of the nervous system as regards its information handling properties, and the like. The first issue of this journal appeared in January 1961.

New Pulsed X-ray Generator

The Zenith Radio Corporation announces the production of an X-ray generator which, it is claimed, produces 1-μsec. pulses of high-intensity radiation, with a repetition-rate of up to 30 per sec. The maximum operating voltage is 150 kV., with a current pulse of 130 amp., and a pulse power of about 20 MW. The radiation beam and the resultant radiographs are observed on a fluorescent screen and an image intensifier, which may be used for cine-radiography. The main use of the apparatus would appear to be in the field of industrial radiography under dynamic conditions. It can be used to study the internal structure of sealed vibrating systems which are not observable optically. In one demonstration the structure of a bullet in flight at 4,000 ft. per sec. was observed on a closed-circuit television system. Possible uses in crystal diffraction work under transient dynamic conditions are suggested. The claims for possible medical uses seem to be on less-firm ground. It is suggested that the very short pulses can give maximum radiographic information with minimum exposure of the patient. This appears to be based on a misconception that information depends on high-radiation intensity only, regardless of the total energy reaching the X-ray film. In one case, sufficient technical information is given for it to be approximately checked, and this raises doubts. It is claimed that adequate density on conventional film is obtained from a single pulse through 1·5 in. aluminium at 6 ft. Simple calculations from the figures given in the report show that such a procedure would involve a conventional radiographic exposure of 0·13 m.amp. and a radiation dose to the film of a fraction of a milliroentgen. Unless there are undisclosed factors, it is very difficult to imagine the production of adequate radiographs under these conditions. In spite of these questions, this new machine offers hopes of important advances in industrial radiography, probably mainly in the field of precision engineering.

Geology of Ben Nevis and Glen Coe

Since the first edition of the *Geological Survey Memoir* on "The Geology of Ben Nevis and Glen Coe" (Scotland : sheet 53) was published in 1916, the district has become somewhat of a national playground, much visited by tourists, mountaineers and parties of geological students. In the second edition (pp. 307, pl. xiii ; H.M. Stationery Office, 1960 ; 35*s*.), Sir Edward Bailey has rewritten and modernized his original publication, to provide a comprehensive account of the classical geological features of this fascinating area. Here one finds, associated with the famous cauldron subsidences, the most spectacular display of plutonic, hypabyssal and volcanic rocks of Lower Old Red Sandstone age known anywhere in Europe ; and the neighbouring Highland schists, with their recumbent folds and anticlines, have given rise to more disputes about structure and succession than any other group of British rocks studied in the past half-century. Although much of the memoir is difficult reading because of its content of local detail, the work will be warmly welcomed by the many geologists who frequent this instructive and scenic corner of Scotland.

Calendar of AGARD Meetings

The Advisory Group for Aeronautical Research and Development (AGARD) of the North Atlantic Treaty Organization announces the following schedule of meetings during April–August 1961 : Aero Space Medical Panel spring meeting (Lisbon, April 10–14) ; Flight Mechanics and Fluid Dynamics Panels, "Stability and Control" (Brussels, April 10–15) ; Flight Mechanics Panel, "*VTOL/STOL* Aircraft" (Paris, April 17–19) ; Ionospheric Research Committee, "Disturbances of Solar Origin on Communications" (Naples, May 15–20); Structures and Materials Panel Symposium on the Material Sciences (Paris, May 15–20); Fluid Dynamics Panel (The Hague, July 17–21); Avionics Panel Technical Meeting, "Microminiaturization" (Oslo, July 24–26); Structures and Materials Panel Specialists' Meeting of the Material Group (Oslo, July 24–26); Eleventh AGARD General Assembly, "Scientific Goals of Space Exploration and Research" (Oslo, July 27–28); Avionics Panel Technical Meeting, "Low Noise Electronics" (Oslo, July 31–August 2).

Methods of Teaching Undergraduates

THE University Grants Committee has appointed the following committee to make a comparative study of undergraduate teaching methods and practices current in the universities and colleges of Great Britain in the fields of arts and pure and applied science: Sir Edward Hale (*chairman*); Prof. R. G. D. Allen, professor of statistics, London School of Economics and Political Science; Dr. D. G. Christopherson, warden, Durham Colleges; Mr. J. S. Fulton, principal, University College of Sussex; Dr. J. H. E. Griffiths, lecturer in physics, University of Oxford; Prof. J. E. Harris, professor of zoology, University of Bristol; Prof. A. G. Lehmann, professor of French, University of Reading; Prof. M. McKisack, professor of history, Westfield College, University of London; Miss M. R. Price, headmistress, Milham Ford School, Oxford; Prof. E. M. Wright, professor of mathematics, University of Aberdeen; Mr. J. S. Morrison, lecturer in classics, University of Cambridge; and Mr. A. Tattersall, University of London (*secretary*).

Announcements

PROF. W. H. MCCREA, professor of mathematics in the University of London (Royal Holloway College), has been elected president of the Royal Astronomical Society, in succession to Prof. R. O. Redman.

LORD HURCOMB, chairman of the Nature Conservancy's Committee for England and a member of its Scientific Policy and Finance Committees, has been appointed chairman of the Nature Conservancy in succession to Mr. Arthur Bryce Duncan, who is retiring from the Conservancy after a long and distinguished period of service.

PROF. A. C. FRAZER, professor of medical biochemistry and pharmacology in the University of Birmingham, has been appointed a member of the Agricultural Research Council, in succession to Prof. K. Mather, who has retired.

PROF. RITCHIE CALDER, professor of international relations in the University of Edinburgh, has been awarded the Kalinga Prize by Unesco for his work for the popularization of science.

MR. R. G. MENZIES, Prime Minister of Australia, is to open a new worsted processing block at the Department of Scientific and Industrial Research's Wool Industries Research Association, Torridon, Leeds, on March 22. Further information can be obtained from Norman Manners, Chief Press Officer, Charles House, 5–11 Regent Street, London, S.W.1.

DR. NORMAN DENNIS NEWELL has been awarded the Mary Clark Thompson Medal of the National Academy of Sciences, in recognition of his outstanding contributions in the field of palæontology and geology, particularly concerning the ecology of modern and ancient calcareous reefs.

THE annual conference of the National Union of Teachers is to be held at the Dome, Brighton, during April 1–6. Further information can be obtained from Mr. F. Jarvis, National Union of Teachers, Hamilton House, Mabledon Place, London, W.C.1. The programme includes an address by Mr. H. D. P. Lee, headmaster of Winchester College, on "Sixth Form Studies", and one by Sir Wilfrid Martineau, chairman of the Education Authorities' Panel of the Burnham Committee, on "Thoughts on Higher Education".

THE Royal Photographic Society of Great Britain is organizing a three-day symposium on "Photography on Expeditions" at the Royal Geographical Society, 1 Kensington Gore, London, S.W.7, during April 11–13. Further information can be obtained from Mr. A. G. Tull, Technicolor, Ltd., Bath Road, West Drayton, Middlesex.

THE spring meeting of the British Radio Spectroscopy Group will be held at the University of St. Andrews during April 6–7. The subjects for discussion are: electron spin resonance in free radicals (April 6) and nuclear magnetic resonance, including high resolution (April 7). Further information can be obtained from D. Bijl and F. A. Rushworth, Department of Natural Philosophy, The University, St. Andrews.

THE Società Italiana di Fisica is organizing an Enrico Fermi international school of physics at Varenna. Five courses are being held as follows: May 23–June 3, cosmic rays, solar particles and space research; June 19–July 1, evidence for gravitational theories; July 3–15, liquid helium; July 17–August 5, semiconductors; August 7–26, nuclear physics. Further information can be obtained from Prof. G. Polvani, Società Italiana di Fisica, Via Saldini, 50–Milano.

THE Institution of Chemical Engineers is holding a one-day symposium in the Chemical Engineering Department, University of Birmingham, on April 12. Among the subjects to be considered are: "Fabrication and Properties of Some of the Newer Constructional Metals" (Dr. N. P. Inglis); "Recent Developments in Wrought Corrosion Resistant Nickel-Base Alloys" (E. Warde); "Plastics in Chemical Engineering and Building" (S. Slaney); "Glass Fibre Wound Laminates" (Dr. F. F. Jaray); "Recent High Temperature Ceramics" (Dr. A. T. Green). Further information can be obtained from T. R. Bott, Honorary Secretary, Midlands Branch, Institution of Chemical Engineers, Chemical Engineering Department, The University, Edgbaston, Birmingham 15.

THE Road Research Laboratory of the Department of Scientific and Industrial Research is holding open days on May 3–4. The work of the Materials and Construction Division and of the Tropical Section will be on show at Harmondsworth, Middlesex, while the work of the Laboratory's Traffic and Safety Division will be on show at the new Road Research Track at Crowthorne, Berkshire. The Scottish Branch of the Laboratory at Thorntonhall, near Glasgow, will be open to visitors during June 7–8. Further information can be obtained from the Press Office, Department of Scientific and Industrial Research, 5–11 Regent Street, London, S.W.1.

THE NUFFIELD FOUNDATION

THE fifteenth annual report of the Nuffield Foundation, covering the year ended March 31, 1960, shows that the disposable income of the Foundation increased by £475,000 to £1,850,000. It welcomes the Charities Act of 1960 as making it easier, speedier and cheaper for a foundation to effect changes in its objects to suit modern needs, and emphasizes the importance of such freedom for the newer type of foundation, in an ever-changing social situation, concerned more especially with the future*. The modern foundation, it is emphasized, is profoundly influenced by the Rockefeller tradition of insistence on search for excellence and its belief that a foundation should evoke from a community a recognition of the need for a particular work the foundation has pioneered, followed by willingness to meet that need out of communal resources.

Of the allocation of £77,260 for science, a further £1,800 was for the work on natural selection and adaptation under Dr. E. B. Ford in the Department of Zoology and Comparative Anatomy, University of Oxford, where Dr. H. B. D. Kettlewell is working on the spread of black moths in manufacturing districts ; their invasion of the surrounding country has shown that resting moths are selectively eliminated by birds and has confirmed that industrial melanism is associated with a physiological superiority of the black moths. A further £4,080 over three years went to the Department of Zoology, University of Liverpool, for work on polymorphism in butterflies and the relation between human blood groups and disease, while £1,000 a year for five years was provided for the Biophysical Research Group then under Prof. A. L. Hodgkin in the Physiological Laboratory, University of Cambridge, for its work on the conduction of impulses in nerve and muscle, active transport or secretion of ions through membranes, and on muscular contractions. A grant of £5,700 over three years, covering the salaries of a senior research fellow and a graduate assistant, and the cost of materials, was made to the University of Liverpool for expansion of the work on the organic chemistry of porphyrins under Prof. E. W. Kenner ; an extended grant of up to £2,950 to the University College of Swansea is to enable Prof. H. E. Street to examine further the culturability of the excised roots of monocotyledonous species, and to undertake a biochemical study of the influence of light on the growth of wheat roots. Of grants totalling £20,000 in technology, £13,500 over five years to Loughborough College of Technology was to integrate the teaching staff with industry, with a further £500 for a study visit to the United States to make a critical analysis of the relation between academic education in colleges and practical training in industry of professional engineers.

Generally, the tendency during the year was towards larger grants, and grants totalling almost £310,000 in medicine included £62,500 over five years for a Nuffield Unit of Clinical Physiology, at the Postgraduate Medical School, Hammersmith Hospital, University of London ; £100,000 to the Zoological Society of London, to found the Nuffield Institute of Comparative Medicine, and create two senior research fellowships ; £60,000 (with a subsequent further £100,000) for a Nuffield Hearing and Speech Centre at the Royal National Throat, Nose and Ear Hospital ; £25,000 over five years to the United Oxford Hospitals for neurological research, including the development of new techniques, the building and maintenance of electro-physiological equipment, and work on the behaviour and structure of the nervous system when affected by disease ; and £18,000 for an extension to the Star and Garter Home for Disabled Sailors, Soldiers and Airmen, Richmond, Surrey. £5,000 over two years was offered to the Institute of Child Health, University of London, for research on biochemical abnormalities and mental retardation, and £6,000 over two years to Guy's Hospital Medical School for investigations into the biochemical basis of temporary psychoses.

In social research and experiment, for which grants totalling £432,000 were made, the Foundation's most important concern was the establishment of a national institute for social work, in accordance with the recommendation of the Younghusband Report, and for this purpose £250,000 was provided. A development fund of £50,000, available at the rate of £10,000 a year, was provided for the Institute of Race Relations, and £11,000 over three years for the School of Oriental and African Studies, University of London, for the first phase of a study of African customary law. Of grants totalling £308,000 in education, £50,000 was to Borough Road Teachers' College, Isleworth, for a science block, to be known as the Nuffield Science Building ; £130,000 to the University of Southampton for the Nuffield Theatre ; and £60,000 to the University of Leeds for the Nuffield Foundation Unit for the History of Ideas, under the direction of Dr. S. Toulmin.

Allocations for the care of the aged and research in ageing, totalling £140,000, included £122,500 to the National Corporation for the Care of Old People, and £7,100 for the Nuffield Gerontological Research Fellowship at the University of Birmingham. From the Oliver Bird Fund, £38,000 over five years was provided to the rheumatism unit at Edinburgh for a second research fellow, a pathologist, and secretarial and technical workers, while the Department of Experimental Pathology, University of Birmingham, received £22,500 over three years in support of studies on plasma proteins aimed at discovering an antiserum specific for rheumatoid factor as a whole, facilitating assay of the factor in human plasma and more precise localization in diseased tissues.

Grants for the Commonwealth overseas totalling £603,000 included £250,000 to the University College of Rhodesia and Nyasaland for a medical school ; £10,000 to the Forestry Department, Entebbe, Uganda, for work on the productivity of tropical high forest ; £20,000 towards the cost of the Library at Jan Smuts House, where the South African Institute of International Affairs is centred ; a further £7,500 to the Gayaza Girls' High School, near Kampala, to enable the diet side of the experiment on farming and balanced diet to be maintained ;

---

* The Nuffield Foundation—Report for the year ended 31 March, 1960. Pp. xiii+144. (London : The Nuffield Foundation, 1960.)

£45,000 for a Nuffield visiting professorship at University College, Ibadan; £20,000 to endow a chair of anæsthetics at the University of Sydney; £40,000 for the recruitment of teachers of English in North Borneo; and £12,000 to establish a Literature Bureau in Sarawak. £25,000 to the Government of Mauritius was for an investigation into food production and marketing, and £4,200 to the University of Otago, Dunedin, and Canterbury Agricultural College for research into the lactation of sheep.

Allocations under the fellowships and scholarships schemes totalled £226,741. These included two new fellowship schemes in medicine, one of which will enable twelve family doctors practising in the United Kingdom to spend six months abroad during the next four years, studying subjects of importance in general practice. The other is for three types of fellowship in pediatrics. No medical fellowships or dental research fellowships were awarded during the year, owing to the absence of candidates of the desired quality, but one medical research fellowship and four fellowships and four scholarships in dentistry were awarded; three travelling fellowships for Civil Servants were awarded. Under the schemes for the Dominions and Colonies, five travelling fellowships in medicine, fifteen in natural science (and one fellowship in engineering from India) and nine in the humanities and social sciences were awarded, but only eight farming awards were made. Two travelling fellowships were awarded to Indian Civil servants. The Foundation's contribution to the Royal Society and Nuffield Foundation Commonwealth Bursaries scheme was renewed at £5,000 a year for a further five years, and twenty-one awards were made.

THE NATIONAL RESEARCH DEVELOPMENT CORPORATION

THE annual report and statement of accounts of the National Research Development Corporation for the year ended June 30, 1960, differs from the usual pattern, information on the position of development projects being mainly placed in an appendix, while the report itself deals at greater length with the Corporation's financial position after its eleven years of life*. The accounts, which are submitted in the form directed by the Board of Trade, with approval of the Treasury, show that annual revenue from exploitation continues to increase, and in spite of the increase in administrative expenses since 1957, the total income of £316,441 almost balanced the total outgoings of £328,961, apart from external development expenditure of £427,316 and interest of £132,096 on Board of Trade advances. The report suggests that the development projects overall, regarded as assets, may in the event provide a greater return than their value written down in the accounts, but in view of the risks involved the Corporation considers it would be unwise to assign to them a higher value at present. It would be easier to present a picture of the success of the Corporation's development activities if development expenditure remained stable for, say, 15 years, but in fact it has increased substantially from £112,988 in 1954–55 to £427,316 in 1959–60, plus forward commitments amounting to £739,000, and the balance sheet thus probably gives an unduly pessimistic picture of the financial position of the Corporation. Future royalty earnings are also expected to be considerably greater than the asset shown, but can only be assessed on a statistical basis from past experience. Meanwhile, interest on the Board of Trade loans continues to grow, and since the Corporation borrows at fixed rates of interest to cover long-term 'risk' ventures at a level of about double its revenue earnings, by the time returns are received on successful projects, the accumulated interest on borrowings to cover both successful and unsuccessful projects will be a formidable sum.

For all these reasons it is still extremely difficult to predict when the Corporation will be able "to secure, in so far as can be done consistently with the fulfilment of their purposes that the return to them from their activities shall be sufficient to meet their outgoings on revenue account". It seems that it may not be possible to recover enough profit from successful ventures to cover both accumulated interest on loans and losses on unsuccessful projects. Meanwhile, in a written answer to a question about the report, the President of the Board of Trade stated in the House of Commons on January 24 that he had asked the Corporation to consider with his Department the possibility of devising some means of ascertaining more readily what the true financial position is, and in particular of assessing the Corporation's ability to commence payment of interest on the monies advanced to it.

In its exploitation activities, the Corporation completed 81 licence agreements in the United Kingdom during the year as against 61 in 1958–59, and 456 such agreements were in force at June 30, 1960. Royalties and other payments under licence and option agreements amounted to £259,000 compared with £182,000 in the previous year, about half these receipts being derived from overseas business. At the end of the year the Corporation held 597 United Kingdom and 1,015 overseas granted patents and 469 United Kingdom and 1,015 overseas patent applications. Of the 1,021 inventions communicated to the Corporation during the year (compared with 681 in 1958–59), 301 were from Government Departments and Research Councils; 44 from Commonwealth official organizations, 137 from universities, 20 from research associations and 8 from charitable organizations. Private firms and individuals in the United Kingdom contributed 478, in the Commonwealth 15, and elsewhere overseas 18. Of the 255 patent rights assigned, 170 were from Government Departments and Research Councils, 70 from universities, and 11 from industrial research associations.

By the end of the year the Corporation was providing financial assistance for 35 development projects covering a very wide technical field, and some of these, such as hovercraft and fuel cell developments, are of a major character and may involve further large capital commitments. Among the new projects for the year are one for the development of electronic automatic equipment for process plant control, Prof. D. Gabor's project for the thermionic generation of electricity, one for the design of an infinitely variable speed gear, and the development of interferon, a substance which has the important property of interfering with the reproduction of normal virus and may be of wide utility against virus diseases. Major revenue earning inventions during the year include cephalosporin *C*, tri-iodothyronine, the *Emidec* 2400 electronic computer, Prof. Wain's selective weedkillers, the Hutchinson–Scarrott pulse height analyser, hecogenin, the carbon monoxide detector, an insecticidal fumer, and a microdensitometer. The Joint Development Committee, set up with the Department of Scientific and Industrial Research in 1958 to examine development problems of common interest and advise on the way in which particular development contracts should be handled, has considered and advised on some twenty proposals for research and development during the year; it has proved a useful forum for considering matters of interest to both bodies, ensures that overlapping is avoided, and facilitates the investigation by both bodies of gaps in research and development in both fields.

ADVISING THE FARMER

WITHIN the Agricultural Education Association, a new section, the Advisory Methods Section, has recently been formed, and a series of papers were read at a meeting of this section in London on December 8. The general topic was to be a review of investigations in advisory methods: in practice, only one of the three speakers dealt at any length with research which has already been done, though all were concerned to analyse the advisory process with a view to further research.

Mr. T. Moore, of the Ministry of Agriculture in Northern Ireland, was the first speaker. He began by discussing the ways in which advisers could be most useful to farmers, and gave it as his view that 'trouble-shooting' was not of great value, by comparison with the giving of advice on the broader topic of farm management. This point of view is not uncommon among farm advisers, though the idea that the person providing the advice is better fitted to say what topics he should advise on than the person seeking the advice seems to have some unfortunate implications. If for no other reason, the adviser may well have to appear willing to do some 'trouble-shooting' if he wants to get invited on to certain farms, and successful 'trouble-shooting' in such circumstances may serve to win the farmer's confidence.

Using an arbitrary classification of farmers into three categories, Mr. Moore pointed out that advisers themselves can often learn a lot from the best farmers, that there will be a second group who cannot be helped much, leaving a third group consisting mainly of hard-working farmers who farm mainly by traditional methods. Farmers in this last group are those to whom advisers can be of most use. He claimed, too, that the size of his farm is not a satisfactory indication of how receptive a farmer will be to advice, though he gave no statistical data to support his claim. Without such evidence, the claim seems an unlikely one, for nearly all studies of farmers have shown that acreage is by far the most useful criterion for assessing the progressiveness of a farmer.

Commenting on advisory methods, Mr. Moore quoted some Australian data which stated that farmers visit other farms a good deal, and he thought this emphasized the importance the farmer attaches to seeing a technique in operation. Another interpretation of the same data would be that farmers feel that they can obtain an unbiased point of view in discussion with a practising farmer. Mr. Moore also commented on individual advisory visits to farms, and remarked that some people were somewhat sceptical about their value. He felt that pilot farms were useful, particularly where the farm chosen is not very different in size from other farms in the district, and claimed it as essential that the pilot farmer farms at a profit, regardless of the appearance of the farm. There seems to be some degree of conflict here with theories of leadership, since farmers commonly appear to have a favourable opinion of farmers who operate on a larger scale than themselves, though there are also data suggesting that the difference in scale must not be too great.

Mr. A. W. van den Ban talked about research on advisory methods in the Netherlands, where there are now five rural sociologists engaged in such work, two of them doing this as a full-time occupation. This certainly compares favourably with Great Britain, in which there is not even one such person who is employed to do full-time research in rural sociology. Mr. van den Ban discussed the part that different sources of information play in the adoption process, with the mass media coming in at the early stages, followed by 'individual' sources, such as talking with advisers, or with other farmers. He recommended that the adviser should manipulate the sources of information at his disposal so as to ensure that the farmer receives information in this way: in practice, because the mass media normally reach a farmer before the 'individual' sources, this does not seem to be any guarantee that this is the ideal way.

Dutch farmers were, until fairly recent times, on a subsistence economy and this still affects their way of thinking. When a whole group of farmers feel this way, it is made even more difficult for an individual to be progressive, and even such activities as reading a book or visiting a meeting in the daytime may be frowned on by the community.

Mr. van den Ban discussed the various sources of information, including the mass media, which a farmer can readily ignore since advice cannot be adjusted to individual needs, as well as farm visits, usually made by an adviser who lives among the farmers he serves, and who does not have so much more training than the farmers: this may mean that there is no great difference in status between the local adviser and the farmers, a fact which should make communication easier. Psychologists have been giving training courses to advisers, in an attempt to help them to cope with problems of inter-personal relationships, for example the somewhat delicate situation which may develop when a young adviser has to tell an experienced farmer, older than himself, how to correct his mistakes.

In the Netherlands, it has been found that most of the progressive farmers have visits from advisers, whereas the traditional ones are less likely to be visited. This is not necessarily bad, as Mr. van den Ban explained, since the traditional farmers may learn from studying what the progressive farmers do. When discussing this, and the more deliberate attempts to promote this type of diffusion process, using pilot farms, Mr. van den Ban pointed out that this mechanism may not operate if the farmer chosen is regarded by others as one who is so skilful, or has such good land, that he is in a different category from themselves. If this occurs, this farmer's example may be ignored because it is felt to be irrelevant to their type of farming.

Mr. van den Ban discussed how farmers who are friends appear to influence each other so that, for example, they are very likely to have the same brand of milking machine. He quoted data to show that farmers felt that attending group discussions had a greater influence on them than attending lectures, and cited data from the United States which appeared to point to the same conclusion. He seemed not to be aware that this American finding has been to some extent discredited by more recent research. Mr. van den Ban concluded by emphasizing the need for directing advisory methods to changing the aims of the community, rather than the aims of individuals, so as not to set the individual in conflict with the community norms.

Mr. H. Burr, of the National Agricultural Advisory Service, gave the last paper. Mentioning the frequently occurring finding that farmers are much influenced by other farmers, Mr. Burr wondered if this could be an artefact due to farmers feeling least damage to their self-esteem by admitting to influences of this kind. This is a fair criticism since these research claims are based on farmers' own reports of what influenced them, though there has been some research recently which shows that farmers will go to a lot of trouble to visit farms where a new technique is being tried, before trying it themselves. With the technique concerned, it seemed likely that a talk with the farmer concerned was being sought, rather than an attempt to learn by seeing the technique in action.

Mr. Burr noted that the National Agricultural Advisory Service as a body strongly favoured the individual advisory visit, but said that some within the Service were trying to 'personalize' group advisory methods, so as to achieve the advantages of both. Mr. Burr also talked about 'leaders', and ways of designating them: self-designation may be misleading and direct-designation, for example, when a pilot farm is chosen by the adviser, has its dangers if the farmer concerned is so different from other farmers that they cannot 'identify' themselves with him. Indirect-designation occurs when farmers are asked to name their leaders, though it is not always easy to be sure that the choice of a farmer whose farm is to be used as a pilot farm, or for a farm walk, does not influence other farmers to regard such a person as a leader. Mr. Burr also pointed out that there are few data to show how much influence such leaders have, nor is it known whether the same farmers are the leaders over a long period. He felt that more should be known about this before the Advisory Service commits itself to using leaders deliberately as an advisory technique.

A lively discussion followed these papers and showed the interest which exists in problems of this type, though, clearly, as the speakers emphasized, much more research is needed. The meeting was, in fact, a most interesting one, and it is to be hoped that this Section of the Agricultural Education Association will sponsor many more. It is heartening to think that a group of people, one of the main tasks of which is to encourage a greater use of scientific advances, should be so concerned to evaluate their own methods of passing on these ideas. D. SHEPPARD

SWISS SOCIETY FOR NATURAL SCIENCES

THE one hundred and fortieth annual session of the Swiss Society for Natural Sciences was held in Canton Aargau during September 23–25, 1960. By a lucky coincidence the main exhibitions connected with the quincentenary of the University of Basle had been extended and were still on view nearby, including the unique Greek treasures and the remarkable display of the University's history, as well as the more purely scientific attraction of the *Oreopithecus* exhibits and the gorilla baby, 'Goma', born in Basle Zoo.

The Aargau meeting opened with a visit to the installations of *Reaktor AG* in a large forest clearing at Würenlingen. Here the first Swiss atomic reactor, *Sapphyr*, originally shown at Geneva, and a second larger reactor are already available for industrial and research purposes in association with Zurich Technical High School. A third reactor, to be larger again, is in process of construction.

The first general assembly was held in the twelfth-century town of Zofingen, cradle of the nation-wide student society Zofingia since 1819, which has been much enlivened by the colourful quinquennial celebrations. Here the central president, Prof. G. Tondury (Zurich), in his address of welcome introduced the opening speech of the annual president, Dr. K. Baeschlin (Aarau), on the main theme of the session, "Der Mensch und seine Beziehungen zur Umwelt". The subject fell into four categories: man and the universe; man and Nature in a geographical sense; man and animal; and man and man. The first two were treated by Prof. M. Waldmeier of Zurich ("Die Beziehung Mensch-Weltall"), and Prof. L. Emberger of Montpellier ("La Relation Homme-Nature") at the first general assembly. The second two, by Prof. O. Koehler of Freiburg in Breisgau ("Die Beziehung Mensch-Tier"), and Prof. W. Loffler of Zurich ("Die Beziehung Mensch-Mensch"), were given at the second general assembly, in the now State-owned Castle of Lenzburg, once (1892–1911) the possession of Lady Mildred Bowes-Lyon and her American husband, Aug. E. Jessup, to whom is due the present good condition of the property, maintained after them (1911–56) by the last private owners, the family of Lincoln Ellsworth, the arctic explorer in partnership with Amundsen.

All four lectures will appear in full in the *Acta* of the Society. Each began with a brief historical survey and underlined lessons to be learnt from the past, but the emphasis was on new knowledge, and some particular aspect was focused in each case. Prof. Koehler illustrated by striking film-sequences the often disregarded capacity of animals to learn, with extreme rapidity, and without direct guidance from man. Prof. Loffler, who had been deliberately chosen as an eminent medical practitioner in preference to a psychiatrist for the subject of human inter-relations, had naturally some words of warning on present-day ethics in his profession, and lent the conviction of intimate experience to the plea for better family relations which both mental and physical welfare specialists endorse to-day, besides surveying the field of modern mass-problems of over-ageing, over-population, hunger and over-production which science must help to solve. Prof. Emberger was inclined to stress the destructive influences of man on Nature more than the work of reclamation by his illustrative slides on this urgent topic of the day. Prof. Waldmeier could not but give much place to modern developments in space-research and the formerly unthinkable extension of experimental techniques to astronomy.

Some of the sectional proceedings were designed to fit into the same general theme of "Man and his Relations to his Environment". A symposium on statistical methods in biology and medicine, organized by the Swiss Society for Medical Biology, in conjunction with the Mathematical Society and the Society for Logic and Philosophy, had for its topics: development and prognosis of the death-rate in Switzerland (P. Nolfi, Zurich); development of the cancer death-rate, with special reference to lung cancer (H. Wiesler, Zurich); medicine and statistics (E. Tanner, Zurich); medicine and logic (E. Batschelet, Basle); optimal information by use of statistical methods (L. Le Roy, Zurich); statistics as an aid to medical research (D. Högger, Zurich).

The medical and psychological scene was prominent also in the historical section, notably in a contribution by Madame A. Virieux of Rolle, "Quelques Remarques à propos de la Psychologie à l'Antiquité", in which she pointed out, among other things, that Plotinus's theory of a two-fold memory—one purely spiritual, one body-linked—influenced Bergson; that the contrast between Socrates, who believed emotion to be entirely governed by reason, and Aristotle, in his recognition of the intimate union of body and soul, is of great relevance to modern psycho-somatic theory. Anxiety as treated by Aeschylus anticipates Freud. The fact that Plato, in his extensive study of vision, took colour to be a subjective phenomenon, in the sense of an original product for each individual of the complex visual process, seems as striking as the subtle and still little-understood fusion he attempted (probably in order to explain the redressing of inverted images) of the two opposing theories of currents emerging from the eye and the object respectively, as the basis of that process.

Psychological and social influences were touched on in a context of recent mathematical history by Dr. R. C. H. Tanner (London) on "W. H. Young et la Méthode des suites monotones", with reference to Young's anticipation by Henri Lebesgue in extending the scope of the Riemann integration process. This discovery was incidental to a much wider field of research for Young, and the setback cannot have made on him the emotional impact assumed by his English biographers, while the role attributed to it in the lack of recognition he received from British appointments boards during his life-time can only, if admitted, impugn the 'cult of results' and lack of methodological insight then common in England; an offshoot perhaps of a competitive and sporting tradition that dies hard.

The mathematical section in its own right made a relatively modest show, because, evidently, of the special effort during June 25–26 in celebrating the Swiss Mathematical Society's half-centenary at Zurich, when the following contributions were made: Prof. M. Plancherel (Zurich) on "Mathematiques et Mathematiciens en Suisse (1850-1950)", Prof. H. Hopf (Zurich) on "Einige neuere Ergebnisse in Differentialgeometrie und Topologie", Prof. G. de Rham (Lausanne) on "Quelques Notions de Base de la Theorie des Variétés Intégrables"—the last two coincided with the international colloquium on "Differential Geometry and Topology", held under the auspices of the International Mathematical Union during June 20–25. At a special ceremony, the topologists Prof. H. Whitney (Princeton), Prof. J. Leray (Paris) and Prof. G. de Rham were honoured and given commemorative scrolls by the annual president of the Swiss Mathematical Society, Prof. H. Jecklin (Zurich).

The physical section concentrated largely on nuclear and allied research; the chemical section also had on its list one paper on the role of heavy metals in the mechanism of radiation damage and shielding (W. Brintzinger, Basle), but for the rest it devoted itself mainly to more classical synthetic and reaction chemistry.

The section for geophysics, meteorology and astronomy heard Prof. Jean Lugeon, head of the Swiss Meteorological Station, Zurich, report on radiosonde measurements in connexion with the industrial air-pollution at Aigle, which he has been actively campaigning against in recent years. J. Riecker, of the same Station, spoke of sunrise in the ionosphere and its repercussions on long-wave propagation. G. Barnes, an Australian who is temporarily at the Technical High School, Zurich, discussed the prevention of water evaporation by surface films. There were also reports on the expedition to El Aaiun in the Spanish Sahara for the total eclipse on October 2, 1959 (Prof. M. Waldmeier of the Federal Observatory, Zurich), and on the unusual fluctuations in the ozone content at different heights in the stratosphere during the sudden heating up in January–February 1958 (H. Dütsch, Zurich). Other communications concerned rain and ice, and climatological problems. In the botany section, the items of special local interest were outweighed by the research work of general import of the strong Geneva school, with F. Chodat and others, and two obituary notices: "W. Vischer 1890–1960", a promoter of the Swiss Society for the Protection of Nature, by M. Geiger-Huber (Basle), and "Eduard Rubel 1876–1960", by W. Lüdi (Zurich).

Two recent international congresses were reported by members who had taken part: that on "Logic, Methodology and Philosophy of Science", at Stanford, by E. Walter (Zurich) and I. M. Bochenski (Freiburg), and that on "Geography", at Stockholm, by E. Schwabe (Berne). R. C. H. TANNER

HEALTH IN INDUSTRY

IN a foreword to a publication issued by the Ministry of Labour, the Minister, Mr. John Hare, directs attention to the fact that more than 300 million working days are lost each year in Great Britain because of sickness or injury.

The Minister's foreword is contained in the booklet, *Health at Work**, which gives fourteen examples of individual industrial health schemes operating successfully in factories in different parts of Great Britain, and the Minister hopes that these examples will encourage other firms to follow suit. The booklet is being widely distributed to factory occupiers by H.M. Factory Inspectorate. It deals with such questions as how factory medical services are organized, and what they achieve, the attitudes of workers to their introduction and the advantages derived by both employer and worker.

In carrying out the survey, the Ministry obtained from each factory details of the nature of the work done there, the organization of the medical services, the work of the medical officers and nursing staff, and the cost of each scheme. Four of the factories employ from 231 to 300 workers; five employ from 500 to 1,000; three from 1,000 to 5,000, and two more than 5,000. Included in the industries represented are heavy engineering and foundry work, copper and metal refining, the manufacturing of electric cookers, refrigerators, electro-plated ware, carbon black, printing machinery, animal feeding stuffs and vegetable oil. Also included are wool and worsted spinning, the processing of asbestos yarns and pipes, and the preparation of insecticides, fungicides, fine chemicals and pharmaceuticals.

Fear about costs is suggested as being the biggest single factor in preventing a more rapid spread of industrial health schemes. The booklet gives detailed figures of the cost of the schemes provided. The annual running costs vary widely according to the nature of the services provided and the numbers employed. Of the 14 schemes described, seven cost £2 or less a head per annum, five cost between £2 and £3, and the other two more than £3. The booklet also mentions an attempt at another factory to weigh in terms of cash the worth or value of such a scheme. This led to the conclusion that, on a conservative estimate, the annual recurring costs of the medical scheme were more than covered by savings in time lost, and that the long-term benefits in better health and morale were a bonus alike to the company and the employee.

It is emphasized that the booklet does not intend to provide a ready-made pattern from which an employer can pick a scheme to suit his pocket, or the size of his factory and his business. What it does show is how, in practice, such schemes are operating to meet particular needs of particular firms, and the considerable variety of functions which the services can perform to the advantage of employers and workpeople. The reasons why firms considered it worth while to spend more money voluntarily on medical supervision varied according to the type of industry, but the following were typical: (1) the pre-employment examination was a safeguard to management and workers; (2) from a practical point of view, speedy attention to accidents and ill-health saved time; (3) improvement in relations between employers and workers resulted from such a scheme.

The general impression drawn from reactions on the part of workers was that schemes of medical supervision described in the booklet provided a personal service which the workers greatly appreciated. The fact that immediate and expert attention could be given to the injured and sick aroused a feeling of confidence among them. The booklet indicates that in one or two instances there was some initial suspicion on the part of workers which soon disappeared with experience of the working of the schemes.

ELM DISEASE

ALTHOUGH the elms are not, nowadays, regarded as important species in forestry proper, the Forestry Commissioners sometimes feel that it is incumbent on them to devote time and money to conduct research into problems concerned with trees in which the British public as a whole are generally interested. A recent publication*, which would have been more correctly described as referring to southern England, deals with such a case. It is concerned with a fungous disease of elms caused by *Ceratostomella ulmi* (Schwartz) Buis., which was first recorded in France in 1918, and in Holland in 1919, and is suspected as having been introduced with elms imported from eastern Asia. It soon became widespread in northern Europe and in North America.

It was first recorded in England in 1927, by which time it was giving much concern to tree-growers in Holland, where its severity at one time earned for it the title of the Dutch elm disease. The effect of the fungus is to cause a vascular wilting of the leaves followed by the death of twigs and branches and even of whole trees. The unsightliness of the dead trees must have attracted the attention of all who travel through those counties where elms are such a notable feature of the landscape. The disease was probably present in Great Britain before its first recording.

The task of studying this disease and of keeping an eye on it was entrusted by the Forestry Commission in 1928 to Mr. T. R. Peace while he was stationed at the Imperial Forestry Institute, Oxford, and he has continued to do this since his appointment to the staff of the Commission, where he is now chief research officer. The present publication, issued by the Forestry Commission, is based on his work, and especially on surveys undertaken by him, during the 31 years up to 1959, but he also acknowledges his debt to American workers in Great Britain in the same field.

---

* Forestry Commission. Bulletin No. 33: The Status and Development of Elm Disease in Britain. By T. R. Peace. Pp. iv+44+76 plates. (London: H.M. Stationery Office, 1960.) 10*s*. net.

This disease is one in which there is a very intimate connexion between two organisms, one from the plant world, the other from the animal world. In 1931 this was established by Fransen, who found that bark beetles of the genus *Scolytus* were carriers of the fungus, which can also enter the tree through wounds and especially through the roots, which, from the suckering habit of the English elm, must be not uncommon.

The surveys revealed that the disease reached its peak in 1931, and that it has steadily declined since 1936–37, not only in the number of elms attacked but also more especially in the severity of the damage caused. It is suggested that the war-time clearance of diseased elms, made possible by the opportunity to market the timber, may have led to a reduction in the beetle population and to infections due to it. It is estimated that the total loss due to the disease lies between 10 and 20 per cent of tree elms, and that this is being made good by sucker growth. Two lines of action were taken to combat the disease. In Holland and the United States a policy of widespread felling of diseased trees was adopted ; in Great Britain things were left to run their course. In view of the considerable degree of recovery of diseased trees, in support of which the author provides many good plates, he is perhaps justified in concluding that the loss of elms would have been much greater in Britain if the first policy had been adopted. He advises the awaiting of the field trials of strains resistant to the fungus before widespread planting of elms in hedgerows or for amenity is undertaken. The disease may long continue as a minor nuisance, but is not expected to bring about the disaster of complete annihilation of the elms immemorial. The great weakness of the investigation undertaken by Mr. Peace is one that is associated with most of the publications of the Forestry Commission, namely, lack of appreciation of the importance of allowing for locality differences. The data in respect of both climate and soil are quite inadequate for the treatment of such an exacting genus as *Ulmus*. When a study is allowed to range over a wide variety of site conditions, it is essential that it should be handled in such a way that site variation is allowed for.

M. L. ANDERSON

PHOTO-EMISSION FROM METAL SURFACES MEASURED WITH GEIGER COUNTERS

By M. A. CONRAD and S. LEVY

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania

DURING the past several years, J. Kramer has investigated a group of phenomena involving the emission of low-energy electrons from solid surfaces. The findings are summarized in two of his papers[1]. This work by Kramer, more recently extended by others, provides an interesting and sensitive new method for investigating the surface condition of both metals and non-metals. Through studies of this so-called Kramer effect, some insight has been gained into a number of phenomena, such as the delayed emission of electrons ('exo-electrons') that occurs when certain non-metals (for example, aluminium oxide powder and gypsum) are crushed or irradiated ; the dependence of photo-emission on surface treatment of metals ; and electron emission caused by heating below the temperature of thermionic emission. For purposes of theoretical interpretation, and determination of possible practical applications, it is essential to know whether these phenomena are inter-related, and to what extent. The purpose of this article is to report some preliminary experimental observations obtained during an investigation of these phenomena in our Laboratory that we believe are pertinent to this problem.

The emission of low-energy electrons from bulk specimens of several metals of commercial purity (aluminium, tin, copper, nickel and zinc), before and after various mechanical treatments (abrasion, filing, polishing and compression), was measured by means of windowless Geiger-flow counters at room temperature. The specimen, in the form of a disk, ¼ in. thick and 1 in. in diameter, formed a part of the cathode ; in one of the counters with a fused quartz envelope, the specimen constituted the largest part of the cathode. The distance of the anode 'point' of the counting tube from the specimen was ¾ in. The tubes were operated in the voltage-range of 1,200–1,300, where the extent of the plateau was at least 150 V. The flowing gas, at atmospheric pressure, consisted essentially of helium (about 98·5 per cent) and contained *iso*butane as the quenching agent ; a small amount (about 0·05 per cent) of water vapour was detected in this gas by mass spectrometry. The background radiation during these measurements was determined to be about 25 counts per minute.

Contrary to the findings of some investigators[2], we detected no emission of electrons from the freshly abraded, filed, or compressively strained metal specimens when the Geiger counters were made completely light tight. In other tests we have made with a quartz-envelope Geiger counter, emission was detected only when the light shielding was not adequate. Evidently, the intensity of stray light needed to induce photo-electron emission from mechanically treated metal surfaces is extremely low. Thus it appears that true delayed emission of low-energy electrons (exo-electrons) does not occur in the absence of any stray light during the detection phase of the experiment.

The blackening of photographic emulsions in contact with freshly deformed or abraded metal surfaces (the so-called Russell effect) is known to result from the formation of hydrogen peroxide at

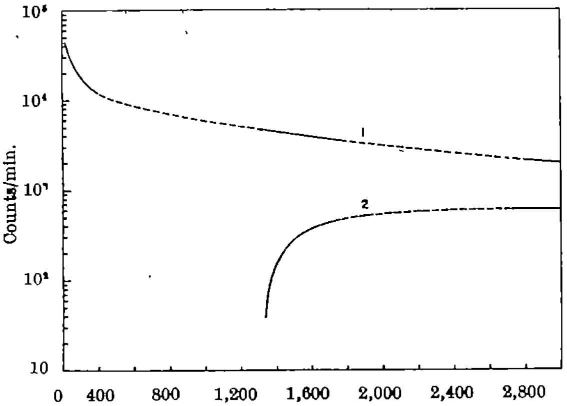

Fig. 1. Photoemission from filed tin surface before and after irradiation. (1) Decay curve of filed tin surface; (2) recovery curve of filed tin after 1-min. irradiation at 50 kV. and 40 m amp. A tungsten target X-ray tube was used. This sample had reached the decay-level of that in curve 1 at the time of irradiation.
Note: Broken lines indicate intervals during which no readings were taken

the metal surface. Grunberg[3] has associated the formation of hydrogen peroxide, in the presence of water vapour and oxygen, with the emission of low-energy exo-electrons. The macroscopic aspects of both the Russell effect and exo-electron emission have been rather thoroughly investigated. Recently, however, Meleka and Barr[4] have applied an autoradiographic technique to a study of the microscopic features of the Russell effect. They found that high-resolution photographic emulsions applied to surfaces of statically strained, high-purity zinc, single-crystal rods were blackened in microscopic areas (lines or rows of dots) corresponding to slip lines associated with varying amounts of slip displacement. In addition, they suggest that exo-electron emission from plastically deformed metals also originates from slip bands on the surface. In view of the fact that we have been unable to detect electron emission from abraded or deformed metal surfaces in complete darkness, it seems to us that the mechanism of the Russell effect cannot be explained by the action of delayed electrons detectable in a Geiger counter.

It is well known that X-ray irradiation of certain non-metals, such as aluminium oxide powder, may induce true delayed electron emission. We have confirmed this observation, and, in addition, have found that the intensity of the delayed electron emission is closely associated with the amount of water contained in the aluminium oxide powder. The emission from samples containing 3 per cent water was about 50 times more intense than that from samples containing about 1·5 per cent water. A similar connexion between electron emission and adsorbed water, during heating and cooling of quinine sulphate, has been reported by Kramer[1].

Our experiments on the X-ray irradiation of metals have demonstrated that such treatment not only does not induce delayed electron emission, but also strongly de-activates the materials with respect to photo-emission. The curves of Fig. 1 show the effect of X-ray irradiation on the photo-emission of a filed tin surface. Other metals have exhibited similar behaviour, with a varying rate of recovery of photo-emission. There is a formal similarity between the 'fatigue' caused by intense light and this de-activation by X-ray irradiation; however, the X-ray fatigue seems to be a more complex phenomenon. Further work is planned to investigate this de-activation by irradiation and the recovery of photo-emission in different atmospheres.

Photo-electric wave-length thresholds were determined by means of the counting arrangement previously described, and a grating monochromator and an incandescent ribbon lamp as a light source. The thresholds were found to be in the near ultraviolet region of the light spectrum, and they differed slightly for the different metals. Table 1 shows the estimated values of these thresholds, together with those reported in the literature for the same pure metals in vacuum.

Table 1. PHOTOELECTRIC THRESHOLDS

	Filed		X-irradiated		Pure metals in vacuum (ref 5)	
	Wave-length (Å.)	eV.*	Wave-length (Å.)	eV.*	Wave-length (Å.)	eV.*
Al	4000	3·07	3500	3·51	2950	4·20
Zn	3600	3·41	3300	3·72	2900	4·27
Sn	3500	3·51	3200	3·84	2820	4·39
Cu	3000	4·09	2900	4·24	2770	4·48
Ni	3200	3·84	3000	4·09	2520	4·91

* Electron volts.

These wave-length thresholds follow, in general, the same order as that for pure metals in vacuum, and differ from them by several hundred Ångström units. No selective maxima in the visible part of the spectrum were found, which agrees with the observations of Sujak[6].

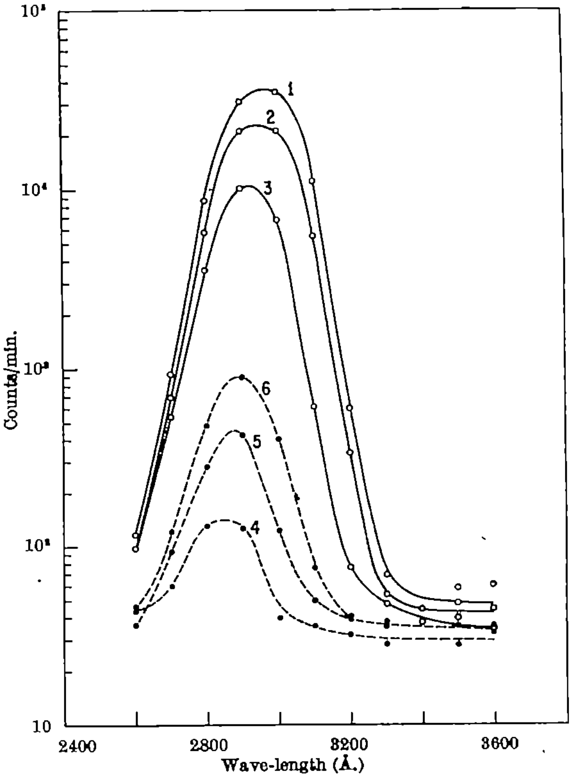

Fig. 2. Decay curves from filed tin, before and after irradiation (1) Immediately after filing; (2) 50 min. after filing, (3) 1,100 min. after filing; (4) immediately after 1-min. irradiation at 50 kV. and 40 m.amp., tungsten target X-ray tube; (5) 35 min after irradiation; (6) 400 min after irradiation
Note: Each point is an average of two readings, symmetrically spaced with respect to the beginning and the end of the run, to minimize the effects of light fatigue

The decay and recovery curves for photo-electric emission from tin, obtained at various intervals after mechanical treatment, are shown in Fig. 2 as a function of wave-length. The maxima in the curves are a result of the combined effects of: (1) a rapid decrease in intensity of the light from the incandescent source with decreasing wave-length, and (2) the rapidly increasing photo-sensitivity with increasing wave-length. These maxima provide a sensitive, qualitative criterion for a shift of photo-sensitivity with change of wave-length. A shift of the maxima of up to 200 Å. was observed in some metals because of differences in surface condition, that is, abraded, irradiated, or after subsequent recovery.

Results such as shown in Fig. 2, as well as other results obtained with a mercury arc light source in the shorter wave-length region of the spectrum, although not yet conclusive, may contribute to an understanding of the increased photo-emission yield resulting from mechanical treatment of metal surfaces. Of particular importance is the question of whether this increase is caused solely by a lowering of the work function of the metal surface. The role of adsorbed gases and oxide films on the metal surface is also of interest.

ACTIVE SENSITIZATION TO TUBERCULIN WITH CELLS FROM TUBERCULIN-SENSITIZED GUINEA PIGS

By Dr. J. L. TURK

National Institute for Medical Research, Mill Hill, London, N.W.7

THE cellular transfer of tuberculin hypersensitivity in guinea pigs was first demonstrated by Chase[1]. Transfer with disrupted peripheral blood leucocytes has been demonstrated in man[2] but not in guinea pigs[3]. After passive transfer, to non-sensitized animals, of live cells from guinea pigs hypersensitive to tuberculin, the recipient may show skin hypersensitivity to tuberculin for 3 months or more. This might be explained by survival of the donor cells or by active sensitization of recipients superimposed on the passive hypersensitivity transferred with the donor cells. The following experiments indicate that the second explanation is probably the true one.

Guinea pigs of the Hartley strain were actively sensitized with tubercle bacilli killed by heat and suspended in a Freund's type emulsion[4]. Spleen cells and lymph node cells were prepared as described previously[4]. Peripheral blood leucocytes were prepared by sedimenting the red cells from blood with 6 per cent dextran in saline and centrifuging the supernatant at 230 *g* for 15 min. The remaining contaminating red cells were then lysed in 0·05 *M* sodium chloride for 1 min. Preparations of peripheral leucocytes from individual animals contained 0·5–2·5 × 10^8 cells, while those from spleen and lymph nodes contained between 5 and 10 × 10^8 cells. Cell preparations were disrupted by freezing and thawing seven times in the presence of 0·1 mgm. deoxyribonuclease (Worthington Biochemical Corporation). Complete disruption of the cells was confirmed under the phase contrast microscope.

Live cell preparations were transfused intravenously, and disrupted cell preparations were injected intradermally into multiple sites on to one flank of the guinea pig. All skin tests were with 40 µgm. tuberculin (Mammalian *PPD*, from the Ministry of Agriculture's Veterinary Laboratory, Weybridge), which had been previously dialysed to remove the glycerol. Skin reactions were read 24 hr. after testing. Tests for anaphylaxis were with 2 mgm. *PPD* intravenously. Skin homografts from the donors of live cells were transplanted according to Billingham and Medawar[5].

The results of the transfusion of ~10^9 live cells from the spleen and/or lymph nodes of individual hypersensitive donors are shown in Table 1. The recipients were grafted with skin from the donors of the cells, and received their first skin test immediately after the transfusion. No correlation was observed between retention of skin graft and persistence of tuberculin sensitivity, and it is therefore very unlikely that the donor cells survived beyond one week. The one guinea pig which retained its skin graft for more than one month was found to have lost its tuberculin sensitivity by this time. Seven of the 13 guinea pigs maintained their sensitivity on repeated testing for more than 3 months, and 6 of these showed anaphylaxis when given 2 mgm. *PPD* intravenously at the end of this time.

Guinea pigs which had received intradermal injections of disrupted cells from hypersensitive donors were skin tested with *PPD* 5 or 6 times over a period of nearly 3 months, as shown in Table 2. Weak sensitivity to tuberculin developed 7–14 days later, in animals that had not had any previous injections of *PPD* and strong reactions were found on re-testing after 17 days. Half the animals showed strong reactions >11 × 11 mm. at some

Table 1. PERSISTENCE OF TUBERCULIN HYPERSENSITIVITY AFTER PASSIVE TRANSFER OF APPROXIMATELY 10^9 CELLS INTRAVENOUSLY

Day of skin test	Number of animals showing skin test reaction (40 µgm. *PPD*) after 24 hr.		Proportion rejecting skin graft	Anaphylaxis (2 mgm. *PPD* intravenous)

	Weak reactions	0	1	—	0	—	0	2
	Anaphylaxis							2 (none died)

* Strong reactions were >10 × 10 mm.; weak reactions 7 × 7 to 10 × 10 mm. † Tested with 2 mgm. *PPD* intravenous.

stage or other and only 2 out of the 18 animals, which were followed over the whole period, failed to show any reaction. As a control, 9 normal animals were skin tested with *PPD* 5 times over a similar period. One of these showed reactivity on the second injection 7 days after the first, and afterwards failed to react, and 2 others showed very mild reactions which appeared only at the end of the three months course. When frozen and thawed peripheral blood leucocytes and spleen cells from normal unsensitized animals were used the recipients behaved like the control group with no cells.

At the end of the experiment all four groups were challenged with 2 mgm. *PPD* intravenously. Sixteen out of 18 animals which had received disrupted cells from hypersensitive donors developed anaphylaxis and 10 died. Only 2 of the 9 controls developed very mild anaphylaxis.

From these results it appears that a transient delayed hypersensitivity is transferred by intact peripheral blood leucocytes, spleen cells and lymph node cells, and that it may be followed by a superimposed active immunization which persists far beyond the time when the donor cells would have been destroyed by a homograft reaction. Peripheral blood leucocytes were more effective in respect of active sensitization than cells from the spleen and lymph nodes. A further property of cells from sensitized donors is that they can enhance the development of antibody against tuberculin accompanying multiple injections of *PPD*. *PPD* is not a single substance, and there is no evidence whether the antibody is directed against traces of contaminating antigen which are known to be present.

These experiments indicate that the possibility that active immunization has occurred must be borne in mind in the interpretation of experiments on passive transfer of delayed hypersensitivity.

I would like to thank Dr. J. H. Humphrey for his advice throughout this investigation.

ENZYMATIC SYNTHESIS OF POLY-β-HYDROXYBUTYRIC ACID IN BACTERIA

By Dr. J. M. MERRICK and Prof. M. DOUDOROFF

Department of Bacteriology, University of California, Berkeley

THE polymeric ester, poly-β-hydroxybutyric acid, originally discovered by Lemoigne in 1927 as a major component of *Bacillus megaterium*, has since been found to be an important storage material in a variety of bacteria[1–4]. It serves as an intracellular reserve of carbon and reducing power in the photosynthetic bacterium, *Rhodospirillum rubrum*, and as the principal substrate for the endogenous respiration of certain aerobes[3–5].

The present report deals with the synthesis of the polymer from carbon-14-labelled D(−)-β-hydroxybutyryl-coenzyme *A* by particulate fractions of cell-free extracts from *B. megaterium* and *R. rubrum*.

Radioactive D(−)-β-hydroxybutyric acid was obtained by alkaline hydrolysis of purified polymer isolated from cells of *R. rubrum* that had assimilated uniformly labelled acetate in the light[3]. The acid was purified by paper chromatography, and the coenzyme *A* derivative was prepared by the mixed anhydride method of Wieland and Rueff[6]. Free β-hydroxybutyric acid was removed from the acidified solution by ether extraction. Analysis of the specific

The reaction mixtures contained either recombined particulate and supernatant fractions (1·08 mgm. polymer and 1·75 mgm. protein per ml.) or resuspended particulate fraction alone (1·08 mgm. polymer and 0·13 mgm. protein per ml.); and the following components (in μmoles per ml.): magnesium chloride, 12·5; glutathione, 12·5; and potassium phosphate buffer, *p*H 7·4, 125.

Exp. 1: particulate + supernatant fractions + 0·48 μequiv. D(−)-β-hydroxybutyryl-coenzyme *A* per ml. (initial); Exps. 2 and 3 particulate fraction + 0·24 and 0·48 μequiv. D(−)-β-hydroxybutyryl-coenzyme *A* per ml. (initial), respectively.

The reaction mixtures were incubated at 33° C.

activity of the product, coupled with hydroxamate and sulphydryl determinations, indicated that at least 95 per cent of the acid was present in thioester combination. Since the commercially available coenzyme *A* used for the synthesis is only 50–75 per cent pure and is contaminated with other sulphydryl compounds (for example, glutathione), the assays reflect the total concentration of β-hydroxybutyryl thioesters, rather than of the coenzyme *A* derivative alone. Poly-β-hydroxybutyric acid was assayed with a modified hydroxamate method for ester determination[7], or by the spectrophotometric method of Slepecky and Law[8].

B. megaterium, strain Km, was grown in the medium containing 2 per cent glucose described by Macrae and Wilkinson[4]. The cells were gathered at the end of exponential growth and washed with 0·033 *M* phosphate buffer, *p*H 7·0. Cell-free extracts were prepared by the osmotic lysis of concentrated protoplasts made by lysozyme treatment of the cells[9]. The lysates were subjected to sonic oscillation to liberate the polymer particles from the cell membranes. The heavy particulate fraction (consisting mainly of polymer particles) was separated from the extract by centrifugation at 3,000 *g* for 20 min. at 4° C., and the particles were washed several times with phosphate buffer, *p*H 7·0. The supernatant fraction contained both the soluble proteins of the cell and the disintegrated cell membranes.

The particulate fraction was incubated with radioactive β-hydroxybutyryl-coenzyme *A* in the presence and absence of the supernatant fraction. The reaction was stopped by addition of alcohol (60 per cent final concentration) and the radioactivity of the isolated polymer was measured. The particles were sedimented by centrifugation, treated with alkaline hypochlorite, washed successively with water and acetone and finally dissolved in chloroform[3,4]. Suitable aliquots were analysed for radioactivity. Controls were performed with reaction mixtures in which β-hydroxybutyryl-coenzyme *A* was replaced by labelled β-hydroxybutyrate in the presence or absence of coenzyme *A*, as well as by alkali-hydrolysed coenzyme *A* derivative. No incorporation of radioactivity into polymer was observed in the control reaction mixtures. In the presence of β-hydroxybutyryl-coenzyme *A*, on the other hand, the polymer became rapidly labelled with carbon-14 when the particulate fraction was used either alone or in combination with the supernatant fraction (Table 1).

The reaction came to completion in about 20 min., at which time 35–45 per cent of the total radioactivity was recovered in the polymer. The observed maximal conversion of thioester to polymer does not give any information on the equilibrium constant for the synthesis of polymer from β-hydroxybutyryl-coenzyme *A*, since the true concentration of the latter compound was not known for reasons previously discussed.

To study the stoichiometry of the reaction, a further experiment was performed in which the disappearance of thioester was measured. The analyses showed that in a reaction mixture initially containing 1·2 mgm. washed polymer particles (without supernatant fraction) and 1·2 μequiv. of thioester per ml., 0·5 μequiv. of β-hydroxybutyrate was incorporated in the polymer, while 0·6 μequiv. of thioester had disappeared. Thus, the synthesis of polymer accounted for more than 80 per cent of the thioester decomposed.

To identify the product unequivocally, the labelled polymer from the above experiment was diluted with purified carrier polymer[3,4] and reprecipitated three times from chloroform: twice with 95 per cent ethanol and once with acetone–ether (2 : 1). The specific activity remained constant throughout. The reprecipitated polymer was hydrolysed for 22 hr. at 30° in *N* potassium hydroxide, treated with cation exchange resin ('Dowex 50', H^+), and chromatographed on paper using the following solvents: (1) ether–benzene–formic acid–water (50 : 50 : 12·5 : 2); (2) *n*-butanol–glacial acetic acid–water (100 : 6 : 25); (3) *n*-butanol saturated with 1·5 *M* ammonia. In each case, only one radioactive spot was found on the paper, which corresponded exactly with the location of the β-hydroxybutyric acid spot.

Cell-free extracts of *R. rubrum* also rapidly incorporate the β-hydroxybutyryl moiety of the coenzyme *A* derivative into polymer. As in *B. megaterium*, the activity is largely associated with the particulate fraction. The kinetics of incorporation are, however, complicated by the presence of an active depolymerase which is also associated with the particles. Crude extracts were prepared by sonic oscillation of cells grown anaerobically in the light. The particulate and supernatant fractions were separated by low-speed centrifuging. The former, which contained the polymer particles, was heavily contaminated with pigmented cell debris. The native polymer, when resuspended in either the supernatant fraction or buffer, underwent rapid hydrolysis to β-hydroxybutyric acid. As much as 80 per cent of the polymer disappeared after 30 min. of incubation at 33° C.

The results of an experiment in which labelled β-hydroxybutyryl-coenzyme *A* was added to a crude cell-free preparation are shown in Fig. 1. Maximal incorporation was achieved within 2 min., after which time the total carbon-14 content of the polymer rapidly decreased. The early termination of incorporation can be plausibly ascribed to exhaustion of the substrate. Thereafter, radioactivity is lost from the polymer as a consequence of the continued depolymerization. The results of a parallel experiment, in which the resuspended particulate fraction was incubated with different concentrations of substrate, are entirely compatible with this interpretation (Table 2). The identification of the carbon-14-labelled product was carried out as described above in the experiments with *B. megaterium*.

No direct activation of β-hydroxybutyric acid with adenosine triphosphate and coenzyme *A* could be demonstrated in cell-free extracts of *R. rubrum*. A small incorporation of carbon-14 into polymer was

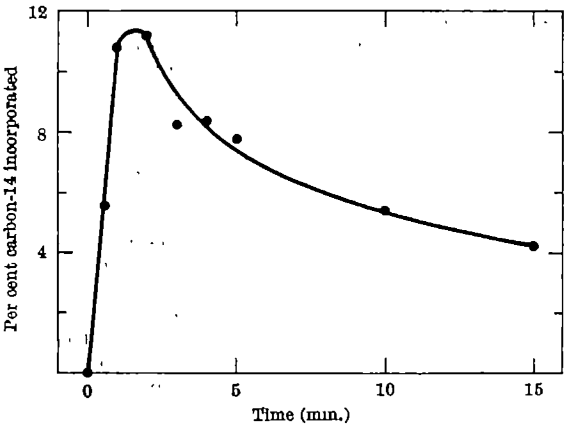

Fig. 1. Incorporation of carbon-14 into polymer by crude extracts of *R. rubrum*. The reaction mixtures contained crude extract (3·9 mgm. polymer and 5·08 mgm. protein per ml.); D(—)-β-hydroxybutyryl-coenzyme *A*, 1·4 μequiv.; and the following components (in μmoles per ml.): magnesium chloride, 12·7; glutathione, 12·7; and *tris* (hydroxymethyl) aminomethanehydrochloride buffer, *p*H 7·4, 127. The reaction mixtures were incubated at 33° C.

observed, however, when crude extracts were incubated with carbon-14-labelled acetate, adenosine triphosphate, coenzyme *A* and reduced pyridine nucleotides.

Two soluble enzymes, presumably involved in polymer metabolism, were found in the supernatant fraction of *R. rubrum* extracts prepared from cells that had depleted their polymer stores. A hydrolytic system catalyses digestion of boiled polymer particles of *R. rubrum* and native polymer particles of *B. megaterium* but does not attack the purified polymer. A specific diphosphopyridine nucleotide-linked D(—)-β-hydroxybutyric acid dehydrogenase is also present in such extracts, and has been partially purified.

Table 2. SYNTHESIS OF POLYMER BY PARTICULATE FRACTION OF *R. rubrum* EXTRACTS

INHIBITION OF CELLULAR RESPIRATION BY CO-CARCINOGENIC FRACTIONS OF CROTON OIL

By DR. A. C. ALLISON and J. W. LIGHTBOWN

National Institute for Medical Research, Mill Hill, London, N.W.7

As a result of the work of Rous and his colleagues[1] and Berenblum and his colleagues[2], it is widely accepted that carcinogenesis in skin—and probably also in other organs—takes place in two successive stages. A single small dose of a carcinogen such as 9 : 10-dimethyl-1 : 2-benzanthracene applied to mouse skin is sufficient to produce a lasting 'initiation' but no tumours. Subsequent repeated application of croton oil gives rise to a large crop of tumours, whereas croton oil applied without a previous initiating stimulus produces few, if any, tumours. Several arguments[3] make it clear that the 'promotion' or 'co-carcinogenesis' by croton oil is complementary to initiation and quite distinct from it; thus, administration of the initiator after prolonged treatment with croton oil does not lead to tumour formation.

The factor or factors in croton oil responsible for tumour promotion have not been identified, and their effects on cell metabolism have not previously been described. Lijinsky[4] has submitted methanolic extracts of croton seeds to silica-gel chromatography and obtained fractions, comprising about 1 per cent of the whole oil, that appear to have all its tumour-promoting activity. Fractions kindly provided by Dr. Lijinsky are at present being analysed by gas chromatography in this Institute in attempts to identify the active agent or agents. In the meantime, the opportunity has been taken—for reasons which will be apparent in the discussion here—to analyse the effects of the croton oil fractions on cell metabolism. It has been found that the highly active tumour-promoting fractions are inhibitors of cellular respiration in several tissues, and this property may well be related to their co-carcinogenic effect.

Rat liver homogenates. Livers of 100-gm. hooded rats were homogenized by the Potter–Elvehjem technique in the following medium: 0·3 *M* sucrose, 0·002 *M* sodium ethylenediamine tetraacetate and 0·03 *M* nicotinamide, adjusted to *p*H 7·1 with potassium hydroxide. Each Warburg flask contained 0·3 ml. homogenate (containing 1·02 mgm. protein nitrogen per ml.), 0·2 ml. potassium succinate, 0·15 *M*, *p*H 7·1 and 1·4 ml. sucrose–ethylenediamine tetraacetate–nicotinamide as above. Croton oil fractions were added in ten-fold dilutions in 0·05 ml. ethanolic solution to give final concentrations from 0·2 to 200 μgm. per ml. Oxygen uptake from air

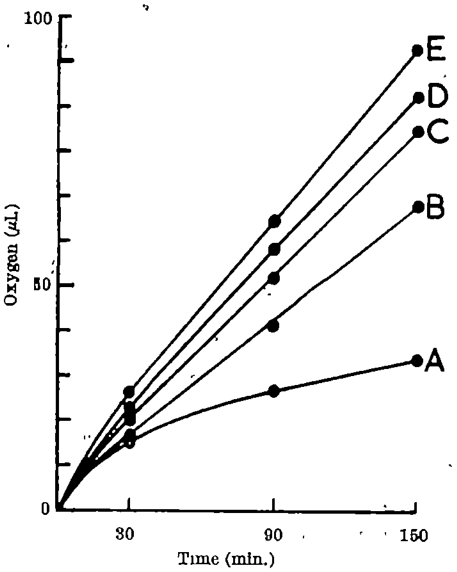

Fig. 1. Inhibition of oxygen consumption of rat liver homogenate with succinate as substrate by croton oil factor in various concentrations: *A*, 200 µgm. per ml.; *B*, 20 µgm. per ml.; *C*, 2 µgm. per ml.; *D*, 0·2 µgm. per ml.; *E*, no inhibitor

was measured in a Warburg apparatus for 2½ hr. at 30°. The results are shown in Fig. 1. Increasing concentrations of croton oil factor caused a progressive inhibition of respiration, up to 70 per cent inhibition at 200 µgm. per ml.

Rat liver mitochondria. Mitochondria were prepared from rat liver homogenates by five sedimentations and resuspensions in sucrose–ethylenediamine tetraacetate–nicotinamide medium. Each flask contained 0·3 ml. mitochondria (containing 0·33 mgm. protein nitrogen per ml.), 0·2 ml. sucrose–ethylenediamine tetraacetate–nicotinamide, 1·0 ml. reaction mixture and 0·1 ml. ethanol + croton oil factor. A reaction mixture devised for prolonged oxidative phosphorylation in rat liver mitochondria was used, giving final concentrations per ml. of: 100 µmol. sucrose, 40 µmol. potassium chloride, 20 µmol. nicotinamide, 1·3 µmol. ethylenediamine tetraacetate, 10 µmol. potassium succinate, 20 µmol. potassium phosphate, 4 µmol. adenosine monophosphate, 0·5 µmol. diphosphopyridine nucleotide, 20 µmol. glucose, 4·6 k*M* units hexokinase and 8 µmol. magnesium sulphate, *p*H 7·1. Oxygen uptake from air at 30° measured in the Warburg apparatus is shown in Fig. 2. The croton oil factor at a final concentration of 100 µgm. per ml. inhibited respiration by 70 per cent.

Mouse skin. Since most of the experiments on co-carcinogenesis by the croton oil factor have been carried out in mouse skin, the effect of the factor on respiration of mouse ear tissues—the metabolism of which is due mainly to skin—was investigated. Four young adult Swiss mice were used. To one ear of each mouse 50 µgm. of croton oil factor in benzene was applied, and to the other ears benzene alone. Four hours later, the animals were killed by dislocation of cervical vertebræ. The ears were cut up into small pieces about 1 mm. square. The pieces from the control ears were placed in two Warburg flasks containing 2·5 ml. Earle's solution with *M*/30 *tris*-(hydroxymethyl)aminomethane buffer, *p*H 7·4, and 0·05 ml. ethanol. The pieces from the ears treated with the croton oil factor were similarly prepared, except that the ethanol contained a solution of the factor, the final concentration of which was 100 µgm. per ml. Oxygen uptake from air was measured in a Warburg apparatus for 2½ hr. at 30°. After the experiment, excess moisture was removed from the tissues by blotting with filter paper; the tissues were weighed, and oxygen uptake corrected for weight. In both flasks containing the croton oil factor oxygen consumption was less than in control flasks, the inhibition being 46 and 52 per cent. These results suggest that respiration in skin, as in other tissues, is inhibited by the croton oil factor.

Heart muscle succinoxidase preparation. The activity of croton oil fractions on a heart muscle sarcosome preparation was also investigated. The method of preparation of material, spectroscopic observation of cytochrome oxidation and reduction and estimation of succinic dehydrogenase using the Thunberg technique were as previously described[6]. Measurements of oxygen utilization in the determination of succinoxidase and cytochrome oxidase activities were made polarographically with a continually cleaned silver electrode in a 3-ml. chamber completely filled to exclude air[7]. Succinoxidase activity was measured in the presence of *M*/50 sodium succinate in 0·14 *M* potassium phosphate buffer, *p*H 7·3. Cytochrome oxidase was measured in the presence of 0·05 *M* *p*-phenylenediamine and 0·14 *M* potassium phosphate buffer, *p*H 7·3. No additional cytochrome *c* was added, and all experiments were carried out at 30°. The final concentration of the heart muscle preparation used was 2·4 mgm. per ml.

Visual observation of the cytochrome absorption bands showed that the croton oil factor at a concentration of 100 µgm. per ml. inhibited the reduction of cytochromes *a* and *c* and the oxidation of cytochrome *b*. The inhibitory effect of various concentrations of the croton oil factor on overall succinoxidase activity is shown in Fig. 3. At a concentration of 50 µgm. per ml. there was also some inhibition of cyto-

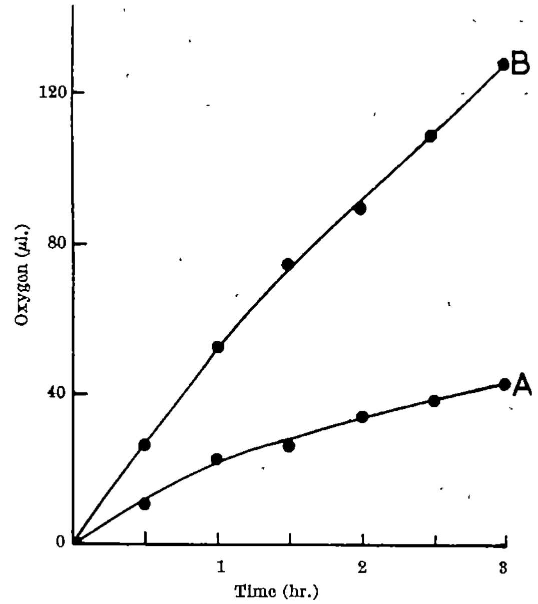

Fig. 2. Inhibition of oxygen consumption of rat liver mitochondria with succinate as substrate by croton oil factor. *A*, inhibitor at a concentration of 100 µgm. per ml.; *B*, no inhibitor

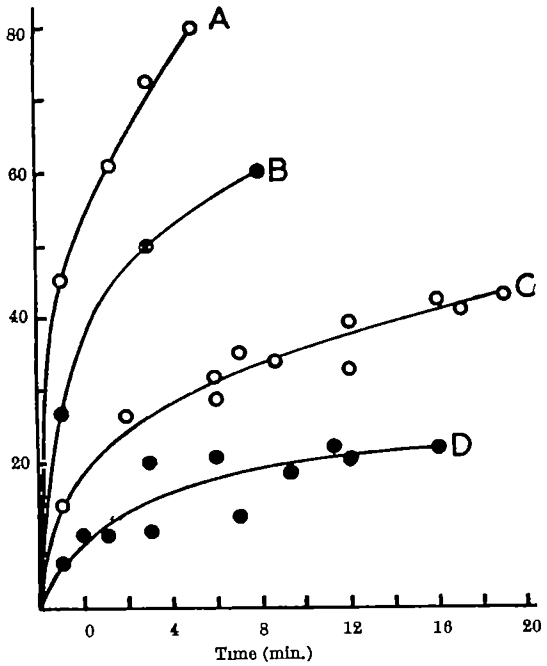

Fig. 3. Inhibition of heart muscle succinoxidase preparation by croton oil factor in various concentrations : *A*, 150 μgm. per ml. ; *B*, 100 μgm. per ml. ; *C*, 50 μgm. per ml. ; *D*, inhibition of cytochrome oxidase by croton oil factor at 50 μgm. per ml.

chrome oxidase, but no inhibition of succinic dehydrogenase. These observations show that the croton oil fraction used has several points of resemblance with antimycin *A* (ref. 8) and quinoline-N-oxide[9] in its metabolic effects. This pattern of inhibition has been shown to indicate a block in electron transport between cytochromes *b* and *c*. The inhibitory effect of the croton oil factor, however, developed more slowly than that produced by antimycin *A* and quinoline-N-oxide, and only the croton oil is also slightly inhibitory of cytochrome oxidase.

In general, the observations we have made suggest that the croton oil factor produces an overall inhibition of terminal respiration mediated through cytochromes. It seems unlikely that the effects reported here are due to alteration of the structural integrity of the cellular particles concerned. Phase-contrast microscopy of rat liver mitochondria exposed to 100 μgm. per ml. of the croton oil factor showed no detectable abnormality. At concentrations of the factor producing marked inhibition of overall succinoxidase activity there was much less inhibition of cytochrome oxidase and no detectable inhibition of succinic dehydrogenase activity.

The results described here show that fractions of croton oil having powerful co-carcinogenic activity contain inhibitors of terminal cellular respiration mediated through cytochromes that are effective in several tissues. It has been found that 100–200 μgm. per ml. of the croton oil fractions produce 70–80 per cent inhibition of respiration in liver and heart muscle preparations. When it is recalled that these fractions are still impure, and that owing to their lipid solubility penetration into tissues in aqueous suspension is poor, it seems likely that the factor or factors inhibiting respiration are highly active. They certainly produce detectable respiratory inhibition in skin at concentrations used for tumour promotion.

The only other metabolic effects of purified croton oil fractions so far described concern active transport of glucose by the isolated surviving guinea pig intestine[9]. The croton oil fractions were found to depress absorption of glucose under aerobic conditions to that observed under anaerobic conditions ; absorption under anaerobic conditions was not affected by croton oil, and other oils were without effect. An interpretation of these results consistent with our own findings is that croton oil depressed the yield from oxidative phosphorylation of adenosine triphosphate required for active transport of glucose. The yield of adenosine triphosphate from glycolysis was not apparently diminished by croton oil, which confirms our impression that the main inhibition is on terminal respiration, with little, if any, effect on other enzyme systems.

It is not yet established that the two properties of croton oil fractions, namely, respiratory inhibition and co-carcinogenesis, are related, but available evidence suggests that they may be. It is well known that tumour cells have high rates of aerobic as well as anaerobic glycolysis[10–12]; tumour cells are also able to use very efficiently adenosine triphosphate derived from glycolysis for protein synthesis[13]. It might therefore be expected that respiratory inhibition would retard growth and division of tumour cells less than that of normal, differentiated cells. In the mouse skin system which has been used for most work on co-carcinogenesis, this supposition seems to be well founded. There is substantial evidence that energy from oxidative phosphorylation is required for division of normal mouse skin cells[14], whereas preliminary results suggest that mouse skin papilloma cells continue to divide when cultured in an atmosphere of nitrogen and carbon dioxide in the presence of adequate glucose (Allison, A. C., unpublished work).

Promotion of co-carcinogenesis can therefore be envisaged as a process by which small numbers of tumour cells (produced by the initiator or carcinogen) are placed at a competitive advantage over normal cells the growth of which is handicapped by respiratory inhibition. Under the continued influence of the promoter, then, it can be supposed that tumour cells can form clones sufficiently large to become self-perpetuating. Experiments with other respiratory inhibitors are in progress to test this hypothesis further.

It should be noted that this hypothesis of carcinogenesis is the opposite of that proposed by Warburg[10]. According to Warburg, cancer cells are formed in two distinct stages : an irreversible lesion of cell respiration comes first ; as a result, some cells die but others become capable of replacing respiration by glycolysis as the main energy-producing reaction and are changed into cancer cells. However, careful search has failed to show substantial impairment of oxidative phosphorylation in tumour cells and mitochondria, and the general conclusion, discussed in detail by Weinhouse[11] and by Schlief and Schmidt[12], is that the high aerobic glycolysis of cancer cells is much less the result of a lesion in respiration than of an enhancement of glycolysis. The evidence thus supports our view that an early change in tumour cells is increased glycolysis, releasing the cells from strict dependence on energy derived from oxidative phosphorylation for growth. The phase of respiratory inhibition does not act directly on tumour cells, as Warburg supposed, but acts as a selective inhibitor of normal cells.

An attractive feature of this hypothesis of co-carcinogenesis is that it not only embraces the effects of anoxia from various causes but can also be extended to include co-carcinogenesis by viruses. Andrewes *et al.*[15] reported that when the fibroma virus—which normally produces benign, regressing lesions—was given to rabbits injected subcutaneously with tar, sarcomata were formed; no tumours were obtained with tar alone. Duran-Reynals[16] produced epitheliomata in the skins of fowls infected with fowl-pox virus and treated with sub-carcinogenic doses of methylcholanthrene; and Rous *et al.*[17] have shown that when the papilloma virus is given to rabbits, the skins of which had been treated with tar, malignant tumours develop rapidly. The nature and timing of the responses in these experiments indicate that the viruses (one of which, fowl-pox, is not a tumour virus at all) are acting as co-carcinogens, their effects being complementary to those of the carcinogens, tar and methylcholanthrene.

A common metabolic pattern in virus-infected cells is increased glycolysis[18], and, if there is competition for phosphate acceptors within the cells as envisaged by Chance and others[19], this would result in respiratory inhibition. Some of the metabolic effects in virus-infected tissues are probably due to interferon, which has been shown to increase glycolysis when added to cells[20]. Indeed, Isaacs[21] has already suggested that interferon may produce conditions favourable for the growth of tumour cells, and so act as a promoter. Increased aerobic glycolysis is a prominent feature of cells infected with the Rous sarcoma virus[22] and the mouse polyoma virus (Allison, A.C., unpublished work), so there is little doubt that these viruses can act as powerful promoters. Whether the tumour viruses—perhaps in contrast to other viruses—can also act as initiators remains to be determined.

We are indebted to Dr. W. Lijinsky for supplying purified croton oil fractions, to Dr. D. B. Roodyn for co-operation in some experiments and to Dr. A. Isaacs for helpful discussion.

MORPHOLOGICAL CHARACTERIZATION OF THE VIRUS OF THE HUMAN COMMON WART (*VERRUCA VULGARIS*)

By M. G. WILLIAMS, A. F. HOWATSON and J. D. ALMEIDA

Ontario Cancer Institute, Toronto

IT is now more than ten years since Strauss *et al.*[1,2] published electron micrographs showing arrays of particles of average diameter 52 mμ in shadowed preparations of extracts obtained from human warts. These particles were believed to be the causative agent of certain types of human warts. Further evidence for the presence of specific particles in human wart tissue was obtained shortly afterwards by Bunting *et al.*[3], who were able to demonstrate arrays of particles within the nuclei of epidermal cells by using the newly developed thin-sectioning technique. The diameters of the particles seen in sections were in the range 20–38 mμ. The smaller size in sections was attributed to differences in preparative procedures. Although techniques for the morphological characterization of viruses have improved considerably since these investigations were carried out, little or no new information about the human wart virus has apparently been obtained. In a recent article, however, Siegel[4] has questioned the conclusion of Strauss *et al.* that the 52-mμ particles represent the human wart virus and has suggested that particles of diameter 16 mμ seen in his shadowed preparations are the causative agent.

In the present article, we describe observations on thin sections of human wart tissue, and on extracts of warts prepared for electron microscopy by the negative staining and shadow-casting techniques. By all three methods numerous particles of well-defined morphology were demonstrated, the most detailed characterization of the particles being obtained by the negative staining method.

Four common warts clinically typical of *verruca plana* and *verruca vulgaris* were examined by the thin-sectioning method. In three of these, the nuclei of some cells in the granular layer, close to the keratin layer, contained uniform particles of mean diameter 46 mμ. Most of the particles consisted of a dense core of diameter 34 mμ surrounded by a less-dense layer of width about 6 mμ, but in some the central region was less dense than the periphery. Fig. 1 illustrates the appearance of a typical group of particles. In one specimen the particles were for the most part arranged in close-packed crystalline formations; but in the others they were scattered at random throughout the nucleus. No particles were seen in the cytoplasm of any of the cells.

Two extracts were prepared, one from eight warts removed from several patients, the other from two warts obtained from two different patients. The warts were ground in a mortar with sand and distilled water and the homogenate clarified by

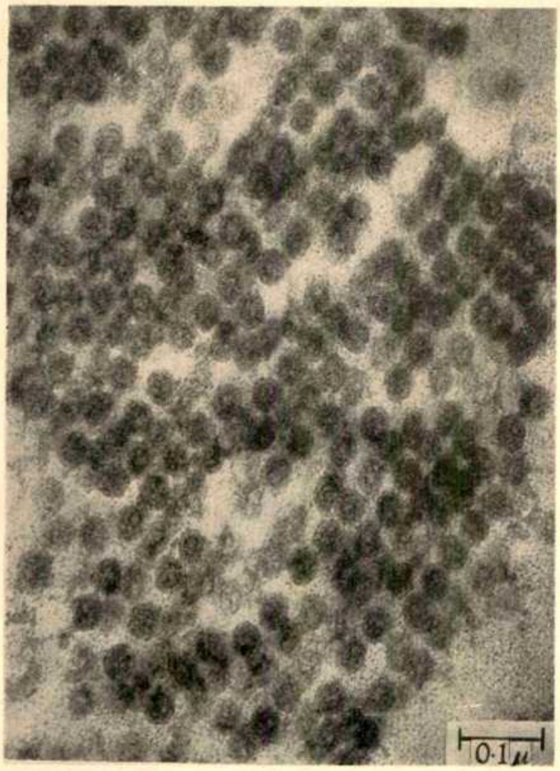

Fig. 1. Thin section showing part of an intranuclear aggregate of virus particles in a cell from the granular layer of a human wart

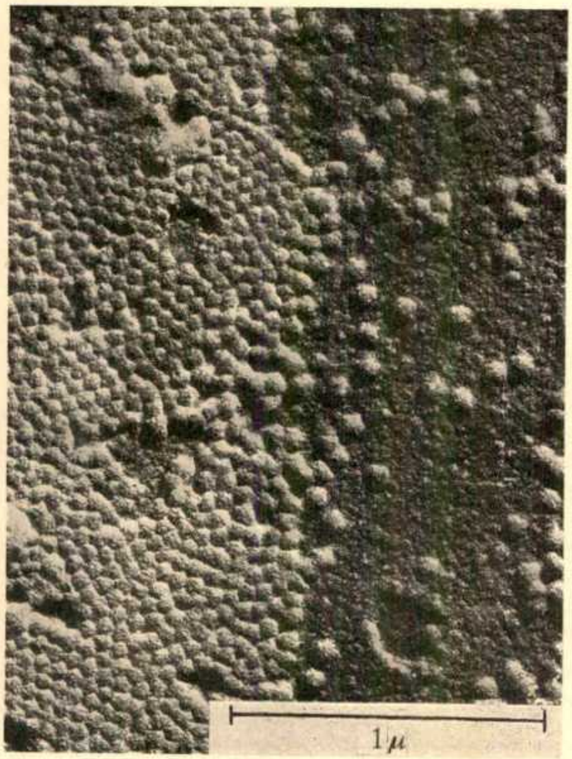

Fig. 2. Shadowed preparation from extract of human warts showing particles both scattered and in close-packed array

low-speed centrifugation. The supernatant was then centrifuged at 35,000 *g* for 2 hr., and the sediment from this centrifugation, re-suspended in a small volume of distilled water, formed the extract. Samples of extracts from both pools of warts were prepared for examination in the electron microscope by standard shadowing techniques, using gold-palladium alloy, and also by the negative staining method[5], using phosphotungstic acid brought to a *p*H of 5·4 with sodium hydroxide.

In shadowed preparations most of the specimen material present on the grid was in the form of particles similar in size and appearance to those described by Strauss *et al.*[1,2]. Fig. 2 shows a typical field. The average diameter of particles in close packed array is 55 mμ. Isolated particles appear appreciably larger, most having a diameter in the range 65–75 mμ. We were unable to detect the 16-mμ particles described by Siegel[4] in our preparations.

Specimens prepared by the negative staining method provided convincing evidence that the particles present in large quantities in our preparations were, indeed, viruses. By this method, it is apparent that the surfaces of the particles are composed of symmetrically arranged sub-units similar to those that have been described for other viruses[6,7]. Fig. 3*a*

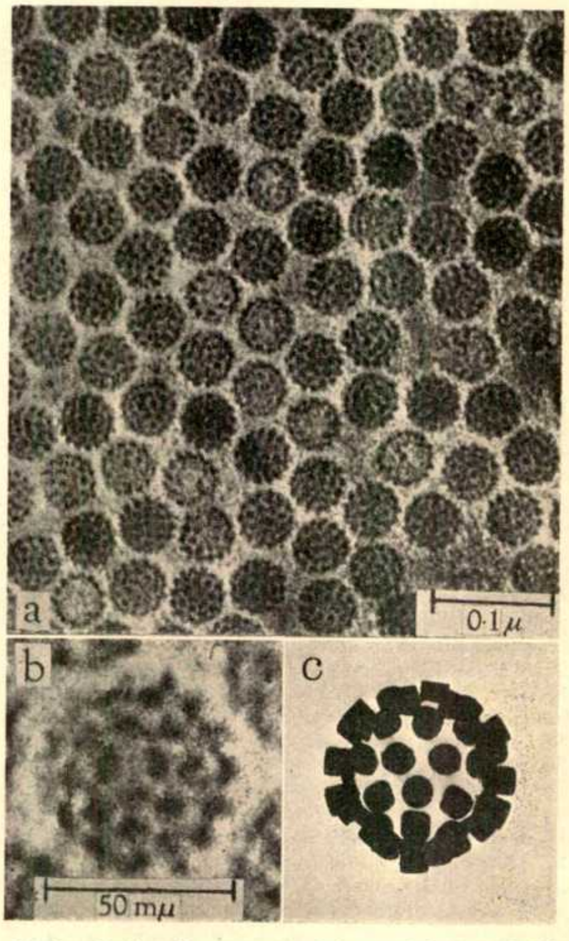

Fig. 3*a*. Portion of an aggregate of virus particles treated with phosphotungstic acid. Symmetrically arranged sub-units are visible on the surfaces of the particles; *b*, single virus particle at high magnification; *c*, model in same orientation as particle showing close correspondence in arrangement of sub-units

shows a small portion of a large aggregate of particles. In Fig. 3*a*, reproduced from a negative print, the sub-units appear dark against a light background. From observations of the arrangement of the sub-units or capsomeres on particles on which they are particularly distinct, it has been deduced that the shell or capsid of the particle consists of 42 capsomeres arranged in 5 : 3 : 2 axial symmetry. Twelve of the capsomeres are situated at the vertices of a regular icosahedron, and the remaining 30 are at the mid-points of the edges between adjacent triangular faces. The capsomeres have a diameter of approximately 8 mμ and are separated from one another by a distance of about 4 mμ. The overall diameter of the particles has an average value of 55 mμ. In Fig. 3*b* is shown an example of a particle in which virtually all the sub-units on one side of the particle are visible. Fig. 3*b* may be compared with Fig. 3*c*, which is a photograph of a model in the same orientation as the virus particle in Fig. 3*b*. In the negative-stained particle the peripheral capsomeres are more prominent than in the model, suggesting that the particle is somewhat flattened, but otherwise the correspondence between particle and model is close.

The number and arrangement of the capsomeres on the wart virus is the same as that established by Wildy *et al.*[7] for polyoma virus. The latter virus, however, is smaller, having a mean diameter of 45 mμ. It is of interest that the wart virus which produces a benign tumour in man is structurally similar to polyoma virus, which produces a wide spectrum of malignant tumours in several species of animals.

HAPTOGLOBINS AND TRANSFERRINS OF TWO TROPICAL POPULATIONS

By Dr. B. S. BLUMBERG and ZORA GENTILE

National Institutes of Health, Bethesda, Maryland

THE haptoglobins are a family of serum proteins characterized by their ability to bind hæmoglobin. They have been studied extensively since 1938 by Jayle *et al.*[1]. Smithies[2] found that human populations could be divided into three types, termed 1–1, 2–2 and 2–1, dependent on their haptoglobin patterns. It has since been shown that for many populations the haptoglobins are determined by two autosomal genes, Hp^1 and Hp^2. Homozygous Hp^1 individuals are type 1–1; homozygous Hp^2 are type 2–2; and heterozygotes are type 2–1[3]. The genetics, and other features of this trait, have been reviewed recently[4,5].

A particularly interesting phenotype is that in which no hæmoglobin binding can be demonstrated. This type (designated *O*) is most common in West Africans[6], but it is also found in other populations[7-9]. There is, as yet, no adequate genetic explanation for this type. There is a striking difference in the distribution of the phenotypes in different populations[10]; and this is presumably due, in part, to differences in the selective forces which operate to maintain this genetic polymorphism. In this regard, it is interesting that there does not appear to be a polymorphism in some lower primates; a haptoglobin band which migrates with approximately the mobility of human haptoglobin type 1–1 was the only one found in a study of 170 *Macaca mulatta* monkeys, 4 chimpanzees, and 34 baboons[11]. Haptoglobin 2–1-like sera are, however, seen in some other species[11a].

Transferrin (or siderophilin) is the iron-binding protein of serum. Most American White individuals have a single iron-binding band, termed transferrin *C*. However, in a small number of American Negroes, and in a larger number of Australian Aborigines, a second band, transferrin *D*, is found; and a fast-moving band, termed *B*, is found in some European and Asian populations. Smithies and Hiller[12] have demonstrated that the transferrins are genetically controlled at a single locus *Tf* by at least three alleles, Tf^B, Tf^C and Tf^D. Transferrins of intermediate frequency, termed B_1, B_2, D_1, D_2, D_3, have also been found, but their genetics is not yet completely determined.

During the 1959 health survey of the Micronesian inhabitants of Rongelap Atoll, Marshall Islands (who had accidentally been exposed to radiation fall-out in 1954[13]) blood samples were collected for hæmatological and other studies. An aliquot of the serum was made available for the present examination.

Rongelap is in the Ralik (Western) chain of the northern Marshalls at approximately 11° N. The inhabitants are Micronesians, an Oceanic group, who have affinities with Polynesians and Melanesians, and, presumably, remotely with inhabitants of south-east Asia. Serum was obtained from 176 individuals, representing 70 per cent of the inhabitants at the time of the visit. Also studied were 118 sera collected in Rongelap in 1957, and kept frozen since their collection. The 1959 collection included nearly all the individuals sampled in 1957.

The West African sera were collected from Nomadic (or Pastoral) Fulani in several regions of northern Nigeria (at approximately 12° N.) in the summer of 1957. The population studied is described in greater detail elsewhere[14]. The red blood cells and serum were separated shortly after collection, and the latter frozen until the haptoglobin and β-globulin determinations were made in 1959. We are indebted to Dr. Hayhurst, medical officer at Pankshin, Nigeria, for supplying 59 of the sera. In all cases, blood was removed by venipuncture and allowed to clot in a dry test-tube at room temperature. The serum was separated by centrifuging and pipetting.

Table 1. DISTRIBUTION OF HAPTOGLOBIN AND TRANSFERRIN TYPES IN RONGELAP AND FULANI POPULATIONS

Population	Haptoglobins									Transferrins						
		1–1		2–2		2–1		0			*CC*		*CD*		*DD*	
	Total No.	No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent	Total No.	No.	Per cent	No.	Per cent	No.	Per cent
All Rongelap	176	59	33·5	31	17·6	83*	47·2	3	1·7	66‡	100	100	—	—	—	—
Rongelap, selected	124	41	33·1	18	14·5	62*	50·0	3	2·4	—	—	—	—	—	—	—
Fulani	84	24	28·6	4	4·8	14*	16·6	42†	50·0	68	57	83·8	10	14·7	1	1·5

* Includes one type 2–1 *M* ('type *F*' of Blumberg *et al.*) (ref. 7).
† Includes two sera in which only the fourth fastest band of type 2–1 was visible.
‡ In addition to the 66 sera studied by the *tris* discontinuous buffer method, 40 were studied by the horizontal borate method and found to be type *CC*.

We used the starch-gel electrophoresis method of Smithies[3], with borate buffer, and the conditions for serum described by him. Approximately 80 per cent of the sera, including all those of haptoglobin type *O*, were also run with the discontinuous (*tris*) buffer system of Poulik[15]. The haptoglobins were identified by adding human hæmoglobin solution to an approximate concentration of 120 mgm. per 100 ml. to serum which was not already hæmolysed, and staining for hæmoglobin with benzidine and hydrogen peroxide[16]. Transferrins were determined by the discontinuous buffer system on 68 Fulani sera and 66 Micronesian sera. In addition, observations on an additional 40 Micronesian sera were made using the borate buffer, horizontal method. No types other than *CC* were seen in the Micronesian sera. All sera which were of phenotypes other than *CC* were also studied by the vertical borate method of Smithies[17]. In confirming the transferrin types of sera other than type *CC*, the position of the protein was confirmed by adding to the serum radioactive ferric chloride (obtained from Abbott Laboratories, Oak Ridge, Tennessee) to a final concentration of approximately 3 × 10^{-5} molar iron, and subjecting the resulting mixture to electrophoresis in the usual manner. Radioautographs of one-half of the slit gel were made by the method described by Blumberg and Robbins[18].

The distribution of the haptoglobin types in the 176 Rongelapese tested is shown in Table 1. This sample includes some families in which two or more offspring are included. In these, all but one sibling were removed by random selection. This resulted in a sample of 124 individuals in which, at most, the parents and one child of a family were included. The distribution of the haptoglobin types in this group did not differ significantly from that in the entire group. In each case, agreement with the Hardy–Weinberg predictions was good, suggesting that the population was homogeneous for this trait. Omitting the three sera with no haptoglobins, the frequency of the Hp^1 gene is 0·58 and of the Hp^2 gene is 0·42. The frequency of the Hp^1 gene is higher than in European populations so far tested.

There were four Rongelapese who had no detectable haptoglobin, either in 1957 or 1959. In addition, there were many sera in which very small amounts only of haptoglobin were visible. This included two which were very faint 2–2's, but in which the fastest-moving haptoglobin band was not seen.

There were two sera (30, 830) which had no detectable haptoglobin, both in 1957 and 1959; in a third (933) only a 1959 serum was available, and this was ahaptoglobinæmic. One serum (842) was a very faint 2–2 in 1957, but ahaptoglobinæmic in 1959. Another (822) was a faint 2–2 in 1957, and in 1959 had a barely detectable amount of haptoglobin, which could not be typed. There was one individual (882) who had a pattern in which the fast-moving haptoglobin band of type 1–1, and the second fastest-moving haptoglobin band of a type 2–1 was present. This is similar to the 'type 2–1 *M*' described by Smithies and Connell[4], which appears to be identical with the 'type *F*' pattern of Blumberg *et al.*[7]. The pedigree of the family with the unusual types is shown in Fig. 1.

The Micronesian sera studied were all transferrin type *CC*. This includes 66 studied by the *tris* discontinuous buffer method and 40 by the horizontal borate buffer method.

The distribution of the haptoglobin types in the Fulani is shown in Table 1. More than half had no detectable haptoglobin, the highest frequency of this type yet reported. Included in the ahaptoglobinæmic sera were two in which only a single band corresponding to the fourth fastest moving band of type 2–1 was visible. This variant had not been seen in any previous studies. Of those who could be typed, nearly 60 per cent were type 1–1, and only four were type 2–2. 15 per cent of the 68 sera had both transferrin *C* and *D*, and one of them had only transferrin *D* (Table 1). Assuming that the genetic hypothesis of Smithies is correct, the distribution of the phenotypes is consistent with the Hardy-Weinberg prediction; and the frequency of the Tf^D gene is 0·1. The serum of the single *D* phenotype was used in studies on the chemical structure of the transferrin to be reported elsewhere[19]. All the slow-moving transferrins had

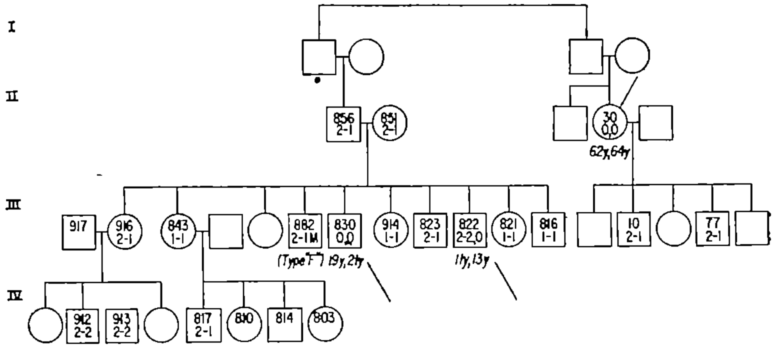

Fig. 1. Kinship of individuals with unusual haptoglobin types (Rongelap. Marshall Islands)

The results of the studies on the 1957 and 1959 sera are shown for those individuals with ahaptoglobinæmia identical mobility, and no fast-moving transferrins were found.

Considerable caution must be exercised in extrapolating to an entire population the gene frequencies obtained from a small sample. This is particularly true when studying societies made up of small isolated or semi-isolated groups in which genetic drift might be expected to operate. Thus, the Rongelapese appear to have a fairly high frequency of type 1–1. However, this may not be the case for all the Marshall Islands. Approximately 60 sera were obtained from each of two other Marshall Islands, Majuro and Utirik. In each of these the frequency of type 1–1 was lower than in Rongelap and closer to the European frequency.

Most of the Fulani sera which could be typed were of type 1–1, and the frequency of the Hp^1 gene was very low indeed. This is consistent with other findings from West Africa[6,10], in which as many as 50 per cent of the samples were of type 1–1. The frequency of Fulani with no haptoglobin is, to our knowledge, the highest yet reported. Each of the *O* types was re-checked two or more times, using the *tris* buffer, and, in addition, approximately half of them were re-checked using the vertical gel method with borate buffer. Only those in which there was no benzidine staining material in the region of the haptoglobins were scored as type *O*.

It is clear from the Micronesian studies that, at least in some cases, an individual may have no haptoglobin at one point in time, but have sufficient haptoglobin to permit typing at another time. (In this case, the interval of sampling was two years.) A complete medical and physical examination and determination of the hæmoglobins, red blood counts, white blood counts, and hæmatocrit were performed on all the ahaptoglobinæmic individuals on Rongelap. No abnormalities which might differentiate them from individuals with typable haptoglobin were noted. Both the individuals, who at one time were typable and at another were ahaptoglobinæmic, were of phenotype 2–2. This was also true in the two cases reported by Galatius-Jensen[9]. However, Sutton *et al.*[10] reported a single individual who was at one time ahaptoglobinæmic but who could later be typed as a 2–1. A further case in point is a patient studied by Shulman and Blumberg[21]. A five-year-old schoolboy developed a hæmolytic anæmia due to the presence of Donath-Landsteiner cold hæmolysis, of unknown ætiology. There were two acute episodes of hæmolysis within 48 hr., but no further evidence of clinical hæmolysis after this. One week after the initial hæmolytic episode, there was no detectable haptoglobin in the boy's serum. One month later, 2 bands corresponding to the second and third fastest bands of type 2–2 were detected. These bound approximately 20 mgm. of hæmoglobin per 100 ml. of serum. Three months after the initial hæmolytic episode, the patient had a normal 2–2 pattern which bound 120 mgm. of hæmoglobin per 100 ml. of serum, approximately a normal amount. However, retesting the serum of the patient one year after the original hæmolysis again failed to detect any haptoglobin despite the fact that there had been no clinically detectable hæmolysis in the interim. Apparently the patient had been intermittently ahaptoglobinæmic and in one case without regard to the presence of the hæmolytic episode. The patient's mother was a type 2–2, but bound an abnormally low amount of hæmoglobin (approximately 20 mgm. of hæmoglobin per 100 ml. of serum).

The ahaptoglobinæmia kinship (Fig. 1) does not help to elucidate the genetics of this type. One of the sibs of an ahaptoglobinæmic was a type 2–1 *M*. Giblett[22] has reported that many ahaptoglobinæmic children were born to matings in which at least one parent had the phenotype 2–1 *M*.

An explanation of the ahaptoglobinæmic type is still not available. In some cases, at least, it appears to vary during life ; and it is known that most infants do not have haptoglobin. The familial clustering, and the association with the 2–1 *M* type, suggest that some inherited factor is involved. The most probable explanation is that there is an inherited propensity to develop ahaptoglobinæmia, and that under different environmental conditions, ahaptoglobinæmia may develop. Under extreme conditions, such as severe hæmolytic anæmia, any individual could develop ahaptoglobinæmia. It is known that other pathological conditions such as liver disease, uræmia and Addison's disease can also lead to a decrease in haptoglobins.

The relatively high frequency of the transferrin types *CD* and *DD* in the Fulani is consistent with the findings in other African groups[22]. On the basis of the small number studied, this appears to be among the highest frequencies found in Africa, and is second only to the prevalence in Australian Aborigines. The complete absence of transferrin *D* in the Micronesian sample is in interesting contrast to the findings on the Fulani. There is no evidence as to what forces maintain this polymorphism in some but not other populations.

We are grateful to Dr. R. A. Conard, leader of the Brookhaven National Laboratory medical survey team to Rongelap, for his assistance in securing the Micronesian blood samples and for his encouragement and help in the conduct of this work. Some of the Fulani blood samples were collected during an expedition to Nigeria supported in part by the Wenner-Gren Foundation, Inc. Mr. O. Oyefesu, Ibadan, assisted in the collection of the Fulani samples.

MODE OF ACTION OF AN ANTHERIDIUM-INDUCING SUBSTANCE IN FERNS

By Dr. ULRICH NÄF

The Rockefeller Institute, New York

THE control of antheridium formation in certain fern species by a naturally occurring substance[1,2] has been reviewed before in detail[3]. The substance is specifically concerned with the formation of male sex organs in many species of the family Polypodiaceæ and the representative tested of the family Dicksoniaceæ, while the species investigated of some other fern families (Cyatheaceæ, Osmundaceæ, Schizaeaceæ) are unresponsive to it[4,5].

The prothalli of *Onoclea sensibilis* and *Pteridium aquilinum* form antheridia in response to the active substance only during an early phase of development. They become insensitive to it soon after they become heart-shaped, and a few days prior to attaining the archegonial phase. Once insensitive, the *Onoclea* prothalli fail to form antheridia even if supplied with the substance at a concentration 15,000 times as high as that sufficient to induce antheridia in prothalli just two days younger[6]. Soon after the prothalli of *P. aquilinum* and of many other polypodiaceous fern species attain the archegonial phase, the last of the ephemeral antheridia formed during the sensitive phase disintegrate.

Czaja[7] and Dopp[8] observed that meristemless fragments excised from the archegonium-bearing prothalli of *Blechnum brasiliense* and of *P. aquilinum*, respectively, proceeded to form antheridia again. Demeristemized, archegonium-bearing *Onoclea* prothalli which were cultured on medium supplemented with antheridial factor also gave rise to antheridia[3]. It has already been mentioned that the archegonium-bearing prothalli of this species are no longer responsive to the antheridial factor. The re-appearance of antheridia in the meristemless fragments shows that the loss of sensitivity to the active substance is maintained as a function of the meristematic region.

Further investigations which were carried out on wings (meristemless fragments), excised from 24-day-old (insensitive) prothalli and cultured on medium containing antheridial factor, showed that the lag period between excision and the first appearance of antheridium initials varied considerably, ranging from 7 to about 14 days[3]. In contrast, most intact prothalli responded to the antheridial factor within 2½–3½ days while they were still at the sensitive stage. Thus the wings excised from the insensitive prothalli formed antheridia with considerable delay. This delay cannot be ascribed to damage incurred by excision because regenerative cell division could be clearly discerned within one day in a few of the wings and within two days in a majority of them. The delay may be understood, however, if we assume that the restoration of sensitivity to the antheridial factor follows excision not abruptly but gradually. Further observations indicated that antheridia arose only in those regions of the regenerating wings that had first undergone a number of vegetative cell divisions[3]. Perhaps, therefore, sensitivity to the antheridial factor is restored as a function of regenerative cell division.

It could be further observed that many excised wings gave rise to antheridia even on medium not supplemented with the antheridium-inducing substance. This is quite surprising if we consider that intact prothalli of this species fail to form antheridia spontaneously under the prevailing conditions of culture[3].

This observation suggests the possibility that meristemless fragments give rise to antheridia without the intervention of the antheridial factor. In turn, such an assumption leads to the hypothesis that the antheridial factor acts by overcoming a block to antheridium formation that is imposed on the prothallus by the meristematic region.

The hypothesis implies that this block to antheridium formation is operative as soon as the prothallus responds to the antheridial factor, that is, at a very early stage of development. In contrast, the prothalli do not become insensitive to the antheridial factor until after they have attained heart shape. The postulated reversibility by the antheridial factor of the newly proposed block also contrasts with the finding that the loss of sensitivity cannot be reversed by that factor[6]. The two phenomena should therefore be treated as distinct events in the development of the *Onoclea* gametophyte.

The present report is concerned with an attempt to put the proposed hypothesis to an experimental test.

The procedures used in the sterilization and inoculation of the spores have been described elsewhere[4,6]. A detailed description of the conditions of culture has also been given. The prothalli were cultured in 50-ml. flasks which contained 10 ml. of the mineral medium solidified with 1 per cent agar. Antheridium-inducing activity was assayed against prothalli of *O. sensibilis* by means of a dilution series. The prothalli of this species proved ideal for this purpose because they failed to form antheridia spontaneously under the prevailing conditions of culture, but formed them readily if the medium was supplemented with antheridial factor[3]. The active substance was supplied as the diluted liquid medium from 7-week-old cultures of *P. aquilinum*, which was commonly active to a dilution of 1 : 30,000 (ref. 2).

With the proposed hypothesis in mind, the formation of antheridia by demeristemized prothalli was studied more closely. Two hundred wings (that is, meristemless parts of the gametophytes) were excised from 16-day-old *Onoclea* prothalli and transferred to new medium in 50-ml. flasks that was supplemented with antheridial factor (supplied as 1/100 full strength *Pteridium* medium that elicited an antheridial response to a dilution of 1 : 30,000). Another 200 wings were transferred to medium not supplemented with antheridial factor. Five wings were cultured in each 50-ml. flask. Samples of 20 regenerating fragments were then examined for the presence of antheridia at intervals of one

Table 1. FORMATION OF ANTHERIDIA BY EXCISED WINGS ON MEDIUM WITH AND WITHOUT ANTHERIDIAL FACTOR

Days after excision	Plus antheridial factor		Minus antheridial factor	
	No. of wings with antheridia	No. of wings with archegonia	No. of wings with antheridia	No. of wings with archegonia
4	0	0	0	0
5	0	0	0	0
6	1	1	0	0
7	5	1	3	1
8	7	2	5	3
9	9	3	8	4
11	11	4	10	6
13	14	8	11	8
15	15	10	9	12
17	13	14	7	17

day or, at later stages of regeneration, at intervals of two days. These observations were continued until the number of antheridium-bearing fragments began to decline. This decline occurs because the regenerating fragments stop forming antheridia when they attain the archegonial phase, as is the case with the prothalli of most polypodiaceous species.

Table 1 shows that the maximal counts of antheridium-bearing regenerates never reach twenty, that is, the number of wings examined at each interval. This indicates that some of the regenerating wings lack an antheridial phase. It seems possible, however, that the antheridia observed on the regenerating wings with an early male phase disintegrate before other regenerates attain this reproductive phase. Thus, the data of Table 1 seem equally consistent with the assumption that all the excised wings form antheridia.

Fifty wings that bore antheridia only 10 days after excision were returned to the medium and re-examined seven days thereafter. Thirty-eight of the fragments then bore 1–4 archegonia. All regenerates with one or two archegonium initials and three out of five wings with three such initials then still bore antheridia. In contrast, the lone fragment which had already given rise to the fourth archegonium lacked antheridia. Whereas these results pertain to wings cultured on medium supplemented with antheridial factor, it was demonstrated that on unsupplemented medium the last-formed antheridia also persist until at least two archegonia have been initiated. The regenerating *Onoclea* wings behave similarly in this respect to intact prothalli of *P. aquilinum*[4].

The wings which attained the archegonial phase up to 11 days following excision in the presence of antheridial factor, or up to 13 days following excision in its absence, invariably lacked antheridia even if they had initiated only the first archegonium. Bisexual wings first appeared among the 20 wings examined two days thereafter. (This is reflected in the fact that the sum of antheridium-bearing and of archegonium-bearing wings then surpasses 20 for the first time ; see Table 1.) Their number increased in the samples examined afterwards, and bisexual wings with up to three archegonial initials could then be seen. It may be concluded that among wings exposed to antheridial factor approximately four wings (that is, the number of wings that have reached the archegonial phase prior to the first appearance of bisexual wings ; see Table 1) to about five wings (that is, 20, the number of wings examined per interval, minus 15, the maximal count of antheridium-bearing wings) out of 20 failed to form antheridia. Based on these same considerations, it is inferred that, among wings not exposed to antheridial factor, about eight or nine out of 20 attained the archegonial phase without a prior antheridial phase. The available data thus permit the conclusion that the maximal counts of antheridium-bearing wings reflect accurately, or with little error, the proportion of wings with an antheridial phase.

As already stressed, the maximal count of antheridium-bearing wings is higher in the presence of antheridial factor (15 out of 20) than in its absence (11 out of 20). The difference was even more pronounced in three repetitions of this experiment. The conclusion was drawn that the addition of the antheridial factor increases the proportion of antheridium-forming regenerates. Table 1 further shows that the first antheridium-bearing fragment appears one day earlier in the presence of antheridial factor than in its absence. Results of the three repetitions are in agreement with the conclusion that antheridium-bearing wings can be seen earlier in the presence of the antheridial factor than in its absence.

Fragments regenerating in the presence of antheridial factor may give rise to antheridia in the interval following the decay of the loss of sensitivity imposed on the wing by the meristem of the mother prothallus and prior to its re-imposition by a newly regenerated meristem. Thus, the regenerates with an early archegonial phase (those with the most rapid rate of regenerative development) would seem to lack an antheridial phase despite the presence of the active substance because this interval is too brief or non-existent.

In the absence of the factor, the phase of regenerative development conducive to antheridium formation is, in the context of the hypothesis, expected to be still briefer if it is recalled that the postulated block to antheridium formation is operative before the loss of sensitivity sets in. It seems predictable, therefore, that, for antheridia to arise in the absence of the antheridial factor, the rate of regenerative development must fall to a still lower value than in the presence of that factor. This consideration may explain the lower proportion of antheridium-forming regenerates in the absence of that factor. It may also account for the delayed appearance of antheridium-bearing wings in the absence of antheridial factor if we consider that wings which first form antheridia in the presence of antheridial factor might undergo regenerative development at too rapid a rate for the formation of these sex organs on medium not supplemented with that factor.

The hypothesis that the excised wings form antheridia without the intervention of the antheridial factor could not remain unchallenged when it was found that the prothalli of *O. sensibilis* produce some antheridial factor even though they fail to form antheridia under the conditions of culture. In the medium, a trace of activity could be first detected at the highest concentration applied (1/2 full strength) 16 days after inoculation. A maximum was reached in approximately 30-day-old cultures when the medium was active to a dilution of 1/10, more rarely 1/30 full strength. The titre remained approximately constant thereafter for a considerable period of time. The 16-day-old prothalli are so small that it was not feasible to obtain a sufficient amount of extract to assay for activity. Extract from 24-day-old gametophytes was active to a dilution of 1/10, more rarely 1/30 strength. As reported earlier, the extract of older, 45-day-old, prothalli was mostly inactive even at 1/2 full strength[8], but some activity could then be regularly detected in the medium. Perhaps this finding relates to the observation that the basal region had become necrotic in many prothalli of that age.

It should be noted that the last individuals of the gametophyte population became insensitive to the antheridial factor 2–3 days before a trace of antheridium-inducing activity could first be detected in the medium. The results thus indicate that *O. sensibilis* fails to form antheridia under the prevailing conditions of culture because the antheridial factor does not become available until all prothalli have become insensitive to it.

The possibility should be weighed that the wings excised from the 16-day-old prothalli give rise to antheridia in response to the small amount of antheridial factor which they probably contain upon excision. Various experiments indicated, however, that the wings do not elaborate the active substance and that the small amount that may be present on excision would become equilibrated with the medium to an ineffective level before sensitivity to the antheridial factor is restored. Even though these results are consistent with the hypothesis that the excised wings give rise to antheridia without the intervention of the antheridial factor, they cannot be considered conclusive. For this reason no attempt is made to describe the experiments in detail.

It should be possible, however, to obtain more conclusive information with young (still sensitive) prothalli which, according to the available criteria, do not yet elaborate the antheridial factor. Attempts to excise non-meristematic regions from such tiny prothalli proved unsuccessful because most or all of the excised cells died. An alternative approach was therefore chosen.

It was demonstrated many years ago[9,10] that plasmolysis of fern prothalli leads to regenerative cell division and the formation of regenerative outgrowths. Plasmolysis is considered to break the cytoplasmic connexions between neighbouring cells. The authors of these papers concluded that the observed regenerative activity resulted from the disruption of cytoplasmic continuity and the ensuing breakdown in correlative interaction between the meristem and the peripheral areas of the gametophyte.

If the postulated block to antheridium formation actually exists as a function of the meristematic region, then the severance of the cytoplasmic connexions might lead to a decay of the postulated block to antheridium formation and, as a consequence, to the formation of antheridia on medium not supplemented with antheridial factor (that is, in the context of the hypothesis, without the intervention of that factor).

Prothalli on about 1½-mm. thick agar slivers were removed from 6-day-old cultures with a spatula and transferred to 30 ml. of the plasmolytic agent in a Petri dish. The agar slivers which were about 3/4 cm.^{2} in surface area were submerged by applying gentle pressure with the flat surface of the spatula, thus ensuring simultaneous onset of plasmolysis in all prothalli. Following an exposure of 35 min. to the plasmolytic agent, the prothalli, on their agar supports, were transferred to 30 ml. of liquid medium in a Petri dish, where they remained for 35 min. The deplasmolysed prothalli were then returned to agar medium, two agar slivers with prothalli per 50-ml. flask. Sucrose, calcium chloride and mannite were used as the plasmolytic agents.

The temporarily plasmolysed prothalli gave rise to antheridia. Each of the three compounds elicited an antheridial response, even at concentrations that brought about only slight plasmolysis (0·4 *M* sucrose or mannite; 0·15 *M* calcium chloride). The prothalli failed to form antheridia when they were treated with non-plasmolytic concentrations of the three substances (0·3 *M* sucrose or mannite; 0·1 *M* calcium chloride).

The demonstration that only plasmolytically active concentrations are effective supports the assumption that the observed antheridia arise as a function of plasmolysis. This postulate is further strengthened by the finding that the spectrum of effective compounds comprises such chemically diverse compounds as an inorganic salt, a metabolically active organic compound (sucrose) and an organic compound which in all likelihood is metabolically inert (mannite). In turn, it is likely, but difficult to demonstrate conclusively, that plasmolysis is effective because of the ensuing disruption of cytoplasmic continuity.

In a few of the prothalli, antheridium initials could first be seen three days after the 6-day-old individuals were plasmolysed (45 min., 0·6 *M* mannite). (An antheridium was considered to be initiated in the context of this investigation when it appeared as the characteristic semi-circular outgrowth on the initiating vegetative cell.) In non-plasmolysed prothalli the first appearance of antheridial initials followed exposure to antheridial factor within 2½ days in both 4- and 6-day-old prothalli and within a wide range of concentrations (1/10, 1/70 and 1/500 full-strength *Pteridium* medium that was active to a dilution of 1 : 6,000). It is possible, however, that slight differences will be found if the interval of observation used (1/2 day) is shortened. All prothalli ultimately formed antheridia at the above concentrations, while only one in about four responded if the concentration was further lowered to 1/2,000 full-strength *Pteridium* medium. At this limiting concentration, an initial was occasionally found again 2½ days after the antheridial factor was supplied if a large enough sample of prothalli were examined. In other instances three days elapsed at this concentration until antheridium initials could first be seen on a few individuals of the gametophyte population.

If the prothalli subjected to plasmolysis at the 6-day stage were provided with antheridial factor (1/100 full-strength *Pteridium* medium) immediately following deplasmolysis, then the lag period appeared to be intermediate between that encountered with plasmolysed prothalli not exposed to antheridial factor and that observed in non-plasmolysed prothalli exposed to the active substance, that is, about 2¾ days elapsed between deplasmolysis and the appearance of the first antheridium initials.

The above results show that the temporary plasmolysis of 6-day-old *Onoclea* prothalli leads to the first appearance of antheridium initials nine days after inoculation. These initials cannot be accounted for in terms of the antheridial factor unless the assumption is made that the factor is present in the 6½-day-old prothalli (nine days minus the interval of somewhat more than 2½ days between the exposure of the plasmolysed prothalli to antheridial factor and the first appearance of antheridium initials).

If the antheridial factor were available to 6½-day-old prothalli in the normal sequence of events, then at least some of the individuals in a population of unplasmolysed gametophytes should give rise to antheridia because all are then sensitive to it (with the spore sample used in these experiments, the first individuals of the gametophyte population became insensitive eight days following inoculation). As repeatedly stressed, however, non-plasmolysed *Onoclea* gametophytes fail to form antheridia at any stage of development under the prevailing conditions of culture. The validity of this argument is further strengthened by the observation that plasmolysis of 5-day-old and 4-day-old prothalli also led to the first appearance of antheridium initials within three days. So far as I am aware, this is the earliest reported onset of antheridium formation among homosporous ferns without an extraneous supply of antheridial factor.

Although these results are consistent with the proposed hypothesis, the alternative possibility should also be considered that plasmolysis hastens the onset of antheridial factor synthesis. An attempt was therefore made to assay for the presence of antheridium-inducing activity. Unfortunately, it was not feasible to obtain a sufficient amount of extract from the tiny antheridium-forming individuals to assay for the presence of such activity in the prothalli. It was observed, however, that young (non-plasmolysed) *Onoclea* prothalli failed to form antheridia if they were inoculated among the temporarily plasmolysed, antheridium-forming prothalli of this same species. In contrast, young (non-plasmolysed) *Onoclea* prothalli did form antheridia if they were inoculated among antheridium-bearing prothalli of the six polypodiaceous fern species tested that formed antheridia spontaneously under the prevailing conditions of culture. All these species secrete the active substance into the medium. In the most closely investigated species, *P. aquilinum*, it was demonstrated that the individual prothallus becomes insensitive to the antheridial factor before it begins to elaborate it at an effective concentration[6]. Accordingly, the antheridia arise in response to antheridial factor in the medium (secreted there by more rapidly growing individuals of the gametophyte population[6]).

These results appear to favour the hypothesis that the temporarily plasmolysed prothalli form antheridia without the intervention of the antheridial factor, due to the decay of the postulated block to antheridium formation. Accordingly, they support the proposed hypothesis that the antheridial factor acts by overcoming a block to antheridium formation that prevents the realization of the genetic potentiality for antheridium formation. Attempts are, nevertheless, being made to design experiments that will permit an unequivocal decision between the two alternative interpretations of the results.

It is hoped that these investigations will contribute toward the solution of the problem as to how genetic potentialities for developmental change are realized at characteristic stages of development and how their realization is, at earlier stages, suppressed.

I am grateful to Dr. A. C. Braun for a critical reading of the manuscript.

This investigation was supported in part by a research grant (*NSF* Grant No. *G*-6144) from the National Science Foundation.

SITES YIELDING HOMINID REMAINS IN BED I OLDUVAI GORGE

By J. DESMOND CLARK

Rhodes-Livingstone Museum, Northern Rhodesia

TOGETHER with Prof. C. Arambourg and Prof. Raymond Dart, I was recently invited by Dr. L. S. B. Leakey to examine the excavations that he and Mrs. Leakey are directing in Bed I at the Olduvai Gorge, Tanganyika.

Bed I consists mainly of volcanic tuffs in the eastern part of the Gorge, but an increasing amount of clay and corresponding reduction in tuffs is observed as one goes westward, so that the westernmost exposures of this Bed consist almost entirely of clays. The tuffs are now all considered to have been laid down under water whereas the bentonitic clay layers with which they are interrelated represent still-water lake deposits. While it was thought by Reck that the coarser beds to the east accumulated fairly rapidly, the clays are considered to have formed only very slowly and in deep water. The edge of the lake shelved gradually, so that periodic fluctuation in water-level would have exposed an appreciable area of the lake margins for temporary settlement. Dr. Leakey states that the fauna includes forms related to the okapi and sitatunga, which indicate a climate wetter than that found at Olduvai to-day and sufficient to maintain swamp and rain-forest. The latter may have been relict patches of an earlier extension, since forms such as lion, cheetah, hyena, horse, hartebeeste and gazelle, which are also represented in the Bed I fauna, usually prefer savannah or grassland country.

We spent up to two days examining the horizons in which the excavations are being conducted, and I had one day in the Coryndon Museum, Nairobi, working on representative collections from the excavations. Besides the main site *FLK*.I from which the skull of *Zinjanthropus boisei* came, we examined three other excavations in Bed I (*FLK.NN*; *FLK.N*I and *MK*.) as well as four in Bed II (*FLK.N*II; *FLK*.II; *BK*.II and *HWK*.II).

At *FLK*.I the *Zinjanthropus* horizon lay on and in the top of 1–2 in. of a thin, bentonitic clay layer, and some 70 ft. × 30 ft. of this had been exposed at the time of our visit. Although most of the floor had been lifted prior to our arrival, a section some 2 ft. × 15 ft. remained, and from this and the horizontal grid plot, the nature of the floor and the position of every find could be clearly seen. The nature of the scatter pattern on these excavated floors is always the same, and the faunal and cultural material lies on the surface of the clay or in the top-most few inches. Similar bone concentrations are absent from the immediately over- and under-lying beds (yellowish tuffs).

The floors, or temporary land surfaces, are usually flat or very gently undulating, and represent exposed and dried mud-flats which became available for temporary settlement by the recession of the lake waters.

Although the usual geological signs of seasonal fluctuation of water-level are absent from the sites, yet it is hard to see how the bone on the living floors could have remained in the unweathered state in which it is found unless the surface had been fairly quickly covered again by the lake waters or unless the mineralization process had begun almost immediately. Bone lying to-day on the surface in the tropics splits up and disintegrates rapidly, and often exposure for only one or two seasons is necessary for chemical and biological agents to destroy it. I have observed that in tropical climates with alternating wet and dry seasons and high diurnal temperatures, the higher the rainfall the quicker bone is destroyed. If, however, the climate when these land surfaces were exposed had been more temperate, with more evenly distributed rainfall and lower temperatures, it is probable that the speed with which bone would be destroyed would be considerably slowed down. I observed on these floors only a few bone fragments which showed evidence of natural weathering, so that unless some such climatic adjustment is postulated it is difficult to understand how the living sites on the surface of the clays could have been exposed for any long period of time before they were again covered. Such exposure and burial must be related to temporary periodic fluctuations in the water-level, perhaps even to seasonal fluctuation, as can be seen occurring to-day around the edge of Lake Manyara, for example.

The faunal and cultural remains occur in a similar manner on each of the three areas where the old land surfaces have been excavated; that is to say, they are scattered in varying concentration over the surface. They consist of broken and sometimes complete bones as well as natural and artificially fractured stone, both quartz and lava. On *FLK*.I, the horizontal plot shows clearly a roughly circular concentration of smaller bone fragments, many small flakes and flake fragments and other worked pieces of quartz and lava over a 15-sq. ft. area. Outside this, the bone and stone occur much more sparsely, except for a rough arc of larger bone fragments and stones a few feet distant on the side from the main concentration.

At *FLK.NN*, artificially fractured and all other stone is very rare, and on some of the faunal remains the marks of teeth, radiating fractures and possible gnawing of the articular ends of long bones suggest that carnivores may have been responsible for part of this accumulation. There is no obvious evidence of carnivore (lion, leopard or hyena) activity at *FLK*.I or *FLK.N*I, however. On these sites the bone fragments consist usually of small sections, splinters and articular ends of long bones and broken mandibles, mainly of pig, antelope and horse, with some reptile and bird bone. Complete animals are never found, so that such parts as are preserved may have been obtained mainly by scavenging.

The number of animals represented on the floors was never large, but it was sufficient to suggest that the remains were carried in rather than that the floor represents a kill site. The shafts of many of the long bones have clearly been fractured to extract the marrow, and the articular ends lie discarded nearby. Sometimes shaft fragments show comminuted fracture on the interior surface, such as experiment shows results from smashing and crushing with a rounded, blunt tool.

Both the natural and artificially fractured lumps of lava and quartz, rarely more than the size of the fist, must have been intentionally carried to the positions where they were found. Every indication is that natural wash must be excluded, and there is never any sand, grit or fine gravel associated with the material on the floors—only the stones and bones lying on the clay. Moreover, as the fractures of nearly all the bones, as of the worked stone, are quite fresh, these floors must, as already stated, have been covered rapidly after their occupation.

The natural stones are likely to have been tools or potential tools just as much as the fractured ones. These last consist of gradations of 'bashing stones', from natural lumps with one or two flakes removed to full polyhedral forms; there are many flakes struck unintentionally from these. Other specimens have been intentionally flaked, usually bilaterally, to form chopping tools, and the flakes stuck from these are also likely to have been used, though, unlike those in Bed II, they show no evidence of intentional retouch or unquestionable utilization. The number and standardization of specimens clearly indicate a regular pattern of intentional manufacture. A statistical comparison of the choppers and polyhedral stones and cores with the flakes and flake fragments from these floors will be of considerable interest and may show whether any of these tools might have been made elsewhere and afterwards carried to the site.

The two horizons in Bed I (*FLK*.I and *FLK.N*I) showed every indication that they were temporary living places of the hominid which made the Oldowan implements and broke up the bones lying on these floors. The evidence we saw excludes any other interpretation. Hominid remains have now been found in intimate association at three horizons in Bed I (*FLK*.I; *FLK.NN*I and *MK*.) and, should no other more advanced form of man be found in this bed, there would be strong reason to accept *Zinjanthropus* as the toolmaker.

I wish to thank Dr. Leakey for making this visit possible and for providing opportunities for discussion with two eminent colleagues. There can be no doubt that these excavations, which have already uncovered so much—from the remains of a complete *Deinotherium*, most of the bones of which had been reduced to a pink powder, to the poison fang of a puff adder—have every possibility of finding the remains of any other hominid, should such have existed contemporaneously with *Zinjanthropus*.

LETTERS TO THE EDITORS

GEOPHYSICS

Southern Hemisphere Fall-out and the Meridional Circulation

THE interpretation of the role of the stratosphere in determining the global fall-out pattern of radioactive debris has recently moved towards a compromise of a number of models.

Libby[1] suggests that a plausible explanation of measurements of the stratospheric burden and of surface fall-out can be advanced in terms of : (*a*) Martell's theory[2] of an 8–12 month residence time for polar latitudes and one of several years for equatorial debris ; (*b*) the Machta model[3] in which the concentration of fall-out in middle latitudes is associated with a meridional circulation in the lower stratosphere[4].

Stewart[5] first suggested that the spring increase in fall-out was a result of such a mean circulation. Libby notes that this concept of stratospheric air rising at the equator, and falling elsewhere, particularly in polar regions, is consistent with an early fall-out for polar injections.

In a previous report describing measurements of total β-activity in rainwater at Melbourne[6], quantitative evidence was advanced that a mean poleward circulation in the lower stratosphere of about 1 m./sec. was largely responsible for the latitudinal spread of debris in the southern hemisphere. The existence of such a circulation is favoured on purely meteorological grounds[7,8].

Further measurements of fall-out presented here give additional support to the idea that the meridional circulation plays a significant part in determining the global fall-out pattern. The results are given in Fig. 1 in the customary units of μμc./l. (The sampling area used was $2 \cdot 2 \times 10^3$ cm.^{2}.) These are also presented in arbitrary units of quantity of material by correcting for decay following Hunter and Bellou[9], on the assumption that half the material is due to the 1958 'Hardtack' tests, and that half originated in 1955. (The latter date represents a compromise between the 1954 'Castle' and 1956 'Red-Wing' tests.) The most drastic revision of this assumption, which is based on Libby's injection results and a two-year stratospheric half-residence time, would affect the shape of the corrected curve by a negligible amount.

The most striking feature of Fig. 1 is the pronounced seasonal variation, with peaks in late 1959 and 1960 occurring roughly during the spring in the southern hemisphere. The peak in early 1959 can be associated with the initial arrival of debris from the 1958 'Hardtack' series. This seasonal variation must be regarded as a meteorological effect since no high-yield tests have been conducted in the southern hemisphere at any time. Stewart's view of an enhanced meridional circulation during the winter is therefore a most attractive explanation.

The total β-activity of fall-out during 1959 measured at Melbourne in the present investigation was 13 mc./km.^{2}, and with the above assumption regarding the time of origin of the debris, a strontium-90 fall-out of 1 mc./km.^{2} can be estimated. This agrees satisfactorily with the value of $\sim 1 \cdot 3$ mc./km.^{2} reported by the H.A.S.L. project for these latitudes[10]. During the same period, stratospheric soundings[11] indicated that the average strontium-90 concentration at 38° S. and 200 mb. was approximately 5 d.p.m./1,000 S.C.F. (that is, 2×10^{-14} c./m.^{3}). If mean vertical motion is solely responsible for transfer across the tropopause, an average vertical velocity of 200 m./day at 200 mb. can be inferred. Somewhat smaller values would be obtained at greater heights.

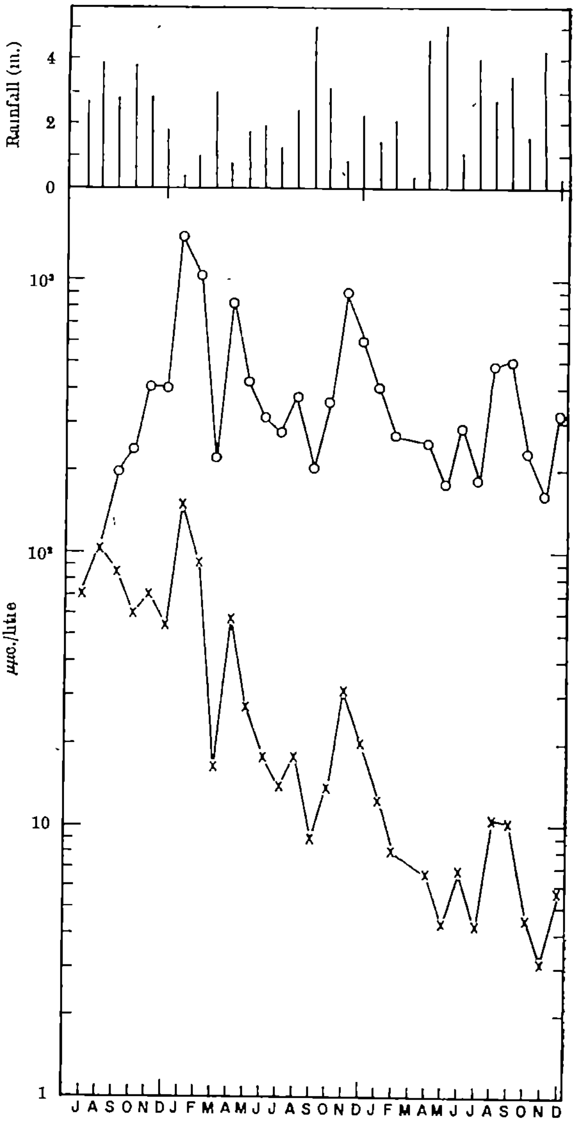

Fig. 1. Monthly fall-out data at Melbourne, Australia. ×, total β-activity ; O, corrected for decay

This is an obvious over-simplification, and estimates of mean vertical velocities of 50 m./day and 120 m./day by Brewer[4] and Priestley[7], respectively, suggest that roughly half the downward movement of debris can be attributed to mean motion and half to eddy transfer.

At our present state of knowledge of stratospheric meteorology there is considerable room for conjecture; but it seems clear that, in interpreting global fall-out, the role of the mean meridional circulation cannot be ignored.

RADIOPHYSICS

Ionospheric Scattering of Satellite Transmissions

RADIO waves from satellites may fade in both regular and random fashion when received with a linearly polarized aerial. Fading due to Faraday rotation or satellite rotation is an example of the former type. Random fades, up to several per second, are sometimes observed, and these have been attributed to scattering from the same kind of ionospheric irregularities as produce radio star scintillation. This fading is more rapid for satellites than for radio stars since it depends on satellite velocity rather than ionospheric drift velocity. Henceforth we shall be concerned only with the randomly fading component.

The 40 Mc./s. transmission from *Sputnik I* has been recorded at Cambridge by Kent[1]. It was observed to fade rapidly at night, but only when the satellite was to the north of Cambridge. The transition to or from this rapidly fading condition was quite abrupt. Kent has concluded that the irregularities which cause the fading are present only to the north of Cambridge; but Mawdsley[2] has suggested that the effect is a natural outcome of the anisotropic nature of irregularities which appear to be aligned with the Earth's magnetic field. Thus, generally speaking, strong forward scattering should be observed only when the satellite is poleward of the observer.

We have recorded the 19·990 Mc./s. transmission of *Explorer VII* at Wellington, New Zealand. Observations commenced recently when details of this satellite came to our notice through the *International Geophysical Year Bulletin*, No. 29, of the U.S. National Academy of Sciences. Table 1 lists the passes during which recordings were made before the orbit moved completely into daylight conditions over Wellington. Scintillations were observed only when the satellite was to the south at night. The transition was abrupt.

Table 1

Date	Local time of pass (approx.)	Remarks
3 6.60	2052–2100	Scintillations when satellite to south
,,	2235–2245	,, ,, ,, ,,
4.6.60	2027–2036	,, ,, ,, ,,
7 6 60	1357–1404	No scintillations
,,	1541–1550	,, ,,
,,	1728–1735	,, ,,
,,	1913–1925	,, ,,
,,	2100–2110	Scintillations when satellite to south

A search of the literature has since brought to light several instances of similar behaviour. They are as follows:

(1) Kraus and Albus[3] made signal strength and Doppler frequency shift measurements of the 20·005 Mc./s. transmission from *Sputnik I* at Columbus, Ohio. Scintillations were recorded as the satellite rose in the north, ceased abruptly as the satellite approached the station, and were absent for the rest of the pass. This behaviour was not apparent on south-to-north passes. It was suggested that an ion cone might precede the satellite, forming an unstable medium for waves passing through it. More recently, Hame and Kennaugh[4] have extended these observations to the 20·005 Mc./s. transmission from *Sputnik III*. They find that scintillation occurs only when the satellite is north of Columbus irrespective of the direction of pass. They have suggested an explanation in terms of changes in magneto-ionic propagation as the Earth's magnetic field varies according to the position of the satellite. It is difficult, however, to see how to explain a change from regular to random fading in this way.

(2) Recordings of signal strength, Doppler frequency shift, and bearing angle of the 20·005 Mc./s. transmission from *Sputnik I* have been made at Komuro, Japan, by Miya *et al.*[5]. Referring to Fig. 2 of their paper, a sudden change in fading pattern was recorded when the satellite was near the station. South of this point the random fading is small compared with Faraday fading. The more intense rapid fluctuation when the satellite is in the north could perhaps be due to scintillation if the recording system had the characteristic of a low-pass filter. Miya *et al.* ascribe the transition as one between line of sight propagation and regular ionospheric propagation associated with ground scattering. However, the transition of Fig. 2 of their paper occurs when the satellite is quite close to the station. Fig. 6 shows fluctuations in bearing angle when the satellite is 'in view' north of the station. The fluctuations disappear as the satellite moves to the south.

(3) Fluctuations in Doppler frequency change at Portsdown, England, of the 20·005 Mc./s. transmission from *Sputnik III* have been noted by Kitchen and Joy[6]. Fig. 3 of their communication shows an example of this behaviour, which is apparent only to one side of the station. The fluctuations have been attributed by these workers to small-scale *F* region irregularities.

(4) Sudden fluctuations in the signal strength at Kiruna, Sweden, of the 20·005 Mc./s. transmission from *Sputnik III* have been reported by Liszka[7]. Fig. 1 of his communication suggests that the fluctuations may be asymmetric with respect to the observing station. Because these fluctuations occur at similar positions for successive orbital revolutions, Liszka has suggested that long-lived heavily ionized tracks are produced by the passage of the satellite through the

atmosphere. This repetitive spatial occurrence is, however, a natural feature of scattering sensitive to aspect from irregularities aligned with the Earth's magnetic field. Although *Sputnik III* may not have passed north of Kiruna (geographically) it is to be noted that, because the magnetic field lines there are nearly vertical, energy may still be scattered from a satellite in the south to an observer in the north.

(5) More recently, Yeh and Swenson[8] have undertaken a detailed analysis of scintillations, observed chiefly on the 20·005 Mc./s. transmission of *Sputnik III*, at Urbana, Illinois. Night scintillation is associated with *F* region and is observed only when the satellite is in the north.

In view of the possible association with radiation belts[9] it would be useful to have scintillation observations over an extended period covering a wide range of latitudes. Few radio stars are suited to this purpose, particularly for the southern hemisphere. Thus, although it may be desirable from some points of view to interrogate the majority of future satellites, there is a strong case for providing a few which transmit continuously at a frequency between about 20 and 40 Mc./s. for some time to come.

In conclusion it appears likely that the night-time scintillation of satellite transmissions demonstrates the ability of field-aligned irregularities to scatter metre wave-length radio waves in a manner highly sensitive to aspect. This is not to be expected of such gross features as are deduced from radio star scintillation or from Kent's observations. Some fine structure must be sought, such as might arise when aggregates of charged particles spiral into the atmosphere along magnetic field lines and create ionized tracks.

ASTROPHYSICS

Galactic Motions in a Large-Scale Magnetic Field

Recent observations on spiral galaxies have shown that their interstellar material cannot be in purely rotational motion. The evidence points to a circulation of interstellar gas between the galactic plane and the galactic halo.

It has been shown for several galaxies[1], including our own[2], that the observed differential rotations will, within less than 10^8 years, transform an initially structureless interstellar cloud into a spiral arm having a pitch like that of observed arms. Since spiral structure presumably persists for longer than 10^9 years, it was suggested that arms may somehow be preserved to 'look young'[2]. However, I[3] have shown that one likely mechanism, magnetic fields embedded in the arms, cannot achieve this; on the contrary, these fields disperse an arm within 10^9 years by their lateral magnetic pressure and an associated transfer of angular momentum. Other evidence that the arms are actually young comes from the observations of Rougoor and Oort[4] that the '3-k. parsec arm', an arm of neutral hydrogen about 3 k. parsec distant from the galactic centre, moves radially outwards with a speed of roughly 50 km./sec. Similar motions have been observed by Munch[5] in the galaxy *M*31. According to observations by Pismis[6] and by Kerr[7], even the well-established spiral arms in our galaxy are moving away from the centre with a velocity of roughly 5 km./sec. At this rate no arms of interstellar gas can remain in the galactic plane after 2×10^9 years unless new arms are formed near the centre.

If the 3-k. parsec arm is a continuing or recurrent phenomenon, the galactic centre is an insufficient source of gas[4]. Furthermore, the 3-k. parsec arm demands a source of angular momentum since it participates in the local circular motions and the angular momentum involved in these motions increases outwards[4]. Hoyle and Ireland[8] investigated the effect of interstellar magnetic fields, but they assumed that the angular momentum gained by the 3-k. parsec arm is derived from elsewhere in the galactic plane. This implies that another cloud of gas should approach the centre, which is not observed. We must, therefore, look to the galactic halo as a source of both gas and angular momentum. The drain of gas from the halo near the centre and the radial motion in the plane imply a return of the gas to the halo. As suggested by Hoyle and Ireland[9], this may occur by means of magnetic bubbles rising from inter-arm regions.

Therefore, both observational and theoretical arguments indicate the existence of a large-scale circulation of the interstellar gas and of its angular momentum between the galactic plane and the halo. Such a circulation can be driven only by interstellar magnetic fields. Davis and Biermann[10] have recently discussed possible models of the galactic halo. They suggest that field strengths of 2×10^{-5} gauss in the plane and 6×10^{-6} gauss in the halo and a gas density of 10^{-2} hydrogen atom per cm.^{3} in the halo are compatible with observations and theory. Although a detailed model of the circulation would be very premature (even the very similar problem of the hydromagnetic dynamo has not been solved satisfactorily), some features may be pointed out which may guide further tests on the possibility of the proposed circulation.

First, superposed on any local turbulence there must be magnetic and velocity fields of a much larger-scale size, of the order of several kiloparsecs. Because of the large electrical conductivity the energy involved in these fields will be dissipated only through interaction with the small-scale turbulence. This is probably small, so that the circulation can be maintained over times longer than 10^9 years and thus preserve the spiral structure of the galactic plane.

Second, since the gas density decreases away from the plane much more rapidly than the field strength, the large-scale field in the halo can control the motion of the gas. This may permit the 'unwinding' of the magnetic fields which have been wound up by differential rotation in the plane and have risen into the halo together with the gas in which they are embedded. The gas being dispersed throughout the halo must stream predominantly along lines of force since the field strength would otherwise decrease proportionally to the gas density. Since the supply of gas and of angular momentum in the halo is comparable to that in the plane, the unwinding of the field and the dispersal of the gas need not occur very rapidly. Probably the field will adjust itself to a rather force-free geometry. But as Schluter[11] has shown, even a perfectly force-free magnetic field can transport momentum and angular momentum. Hence a circulation of energy and of angular momentum appears possible, with the gas moving radially outwards in the plane, gaining energy and angular momentum from gas moving inwards through the halo.

Finally, I have attempted to make some estimates on the forces acting on the gas at the centre and in the 3-k. parsec arm. For this purpose I assume that the large-scale magnetic field within regions of high gas density is axisymmetric, although no such symmetry is to be expected outside these regions. The assumption is justified primarily by the conclusions which can be drawn from it. Let R and θ denote the distance from the centre and the angle in the direction of the galactic rotation. The rate of transfer of angular momentum to a unit mass of gas in the galactic plane at a density ρ is (in c.g.s. and gauss units):

$$\frac{d}{dt}(Rv_\theta) = \frac{H_R}{4\pi\rho}\frac{d}{dR}(RH_\theta)$$

On the assumption that the field lies parallel to the trailing arms we find that H_θ and H_R have opposite signs. The quantity $|RH_\theta|$ must attain a maximum at some $R = R^*$ since it vanishes at the centre and decreases outwards at the edge of the galactic plane[12]. The gas within R^* loses angular momentum and must be moving inwards; the gas outside R^* gains angular momentum and moves outwards. Hence gas must condense on to the galactic plane near R^*. Presumably it moves at different rates on either side of R^*. I conclude that on each side of the galactic plane there must exist two circulations which meet on a surface through R^* but do not interfere with each other. This implies that the magnetic fields are self-contained and angular momentum is conserved in each circulation. The neutral hydrogen within 1 k. parsec from the centre is observed not to expand with the surrounding 3-k. parsec arm[4]. Accordingly, I identify $R^* = 1$ k. parsec and make the following numerical estimates for the outer ($R > 1$ k. parsec) circulation, which involves all the spiral arms: near the Sun, $H_\theta = 2 \times 10^{-5}$ gauss; near $R = 4$ k. parsec, $H_\theta = 4 \times 10^{-5}$ gauss (negligible transfer of angular momentum outside $R = 4$ k. parsec); and at the 3-k. parsec arm, $H_\theta = 7 \times 10^{-5}$ gauss, $H_R = -0{\cdot}25\ H_\theta$, $\rho = 0{\cdot}4$ hydrogen atom per cm.[3]. The resulting transfer of angular momentum permits the 3-k. parsec arm to move radially outwards with a speed of about 50 km./sec. and still to participate in the local circular motions. Thus the assumption of axisymmetry within regions of large gas density results in the explanation of the isolated central region and of the velocity of the 3-k. parsec arm. Furthermore, these estimates imply that gas may rotate more slowly than stars at the same R, since the gradient of the magnetic field causes forces on the gas which partly balance the galactic gravitational attraction.

Some Solar Lines in the Infra-Red Spectrum observed from a High-Flying Aircraft

In a previous communication[1], it was pointed out that strong absorption by atmospheric constituents obscures large parts of the infra-red spectrum from ground-level observation. However, by working at high altitudes and by using a high-resolution spectrometer, it is possible to observe additional features due to absorption in the solar atmosphere. Among these are two absorption lines due to the electronic transitions in solar hydrogen 3–4 and 4–8, which occur in the great water-vapour band at 1·9μ.

These lines, which have not previously been detected because of obscuration by water-vapour absorption—even at mountain observatories—are clearly observed at 40,000 ft., as shown in Fig. 1. They remain of the same intensity at higher altitudes, thus confirming their solar origin.

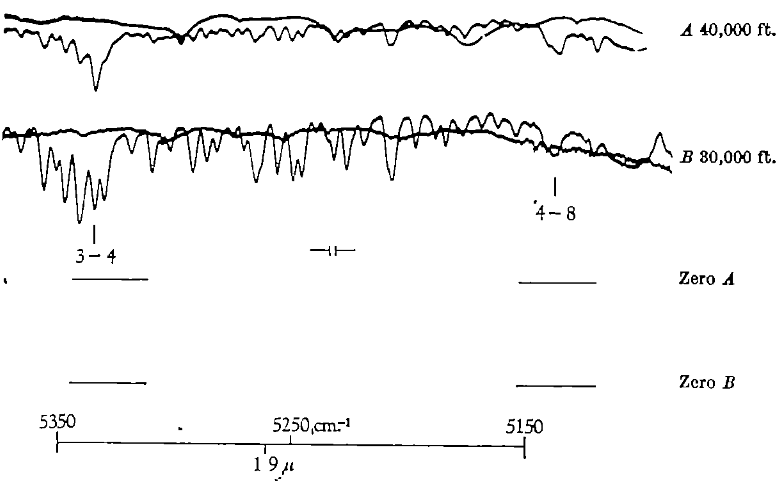

Fig. 1

Another solar line which we have now detected at high altitudes is the 4–6 transition, lying in the $2\cdot6\mu$ water-band. The presence of this line will produce slight corrections to some of the water-vapour concentrations calculated by Houghton and Seeley[2].

Full results of our measurements are being submitted to the Royal Society for publication in the *Philosophical Transactions*.

PHYSICS

Line-Spread Functions of Photographic Emulsions

The detail-recording ability of a photographic emulsion may be tested by exposing it through a very narrow slit, and, after processing, measuring the variation of density with distance, x, from the centre line of the image. When the scale of density is transformed into a scale of effective intensity of illumination, the result is the line-spread function, $B(x)$.

Traditionally, the 'double-exponential' function[1-3] is taken as a convenient model for the analytical representation of measured results. For the present purpose, this function may be expressed as :

$$B(x) = \pi F \quad \exp(-2\pi F|x|)$$

Its Fourier transform, the sine-wave response function, is :

$$Y(f) = 1/\{1 + (f/F)^2\}$$

where f is the spatial frequency and F is the value of f such that $Y(F) = 0\cdot5$. In generalized form, these functions are shown as the dashed curves in Figs. 1 and 2. Some workers, however, have indicated dissatisfaction with this model, referring either to its physically unlikely sharp peak and central discontinuity or to the related slow fall of sine-wave response at the higher frequencies. Various modifications have been proposed, but most involve at least one additional parameter.

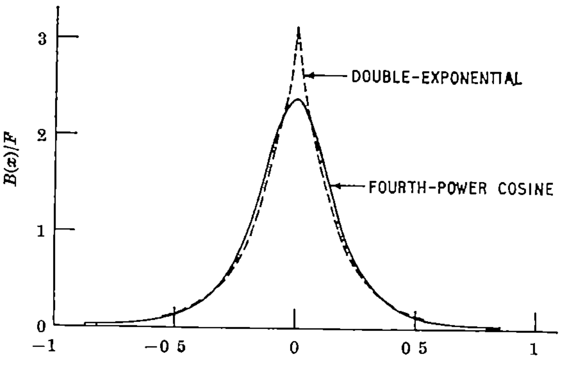

Fig. 1. Line-spread functions

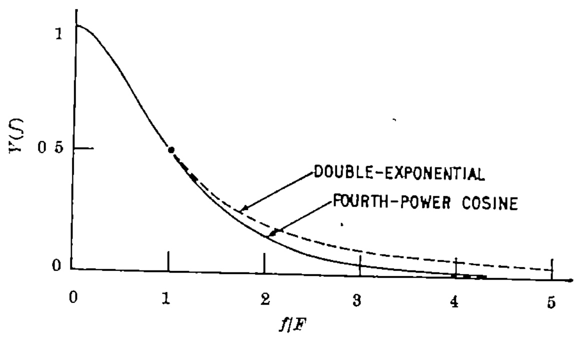

Fig. 2. Sine-wave response functions

In the course of work on television image structure, it has been noticed that the 'fourth-power cosine' function, as it may be termed, offers advantages as a model line-spread function. Expressed in terms of a length parameter, D, the function is :

$$\begin{aligned} B(x) &= 2\cos^4\{\tan^{-1}(x/D)\}/\pi D \\ &= 2/\pi D\{1 + (x/D)^2\}^2 \end{aligned}$$

or, in terms of the parameter F already defined :

$$B(x) = 2AF/\pi\{1 + (AFx)^2\}^2$$

where $A = 3\cdot7437$. The corresponding sine-wave response function is :

$$\begin{aligned} Y(f) &= (1 + 2\pi Df)\exp(-2\pi Df) \\ &= (1 + 2\pi f/AF)\exp(-2\pi f/AF) \end{aligned}$$

Generalized in terms of F, these functions are shown as the full-line curves of Figs. 1 and 2.

Comparing the curves in Fig. 1, it will be seen that the fourth-power cosine function is closely similar to the other in the region of the 'skirts', but it has the desirable property of being less-sharply peaked and there is no central discontinuity. The related features in Fig. 2 are the similarity at the lower frequencies and the more-rapid fall at the higher frequencies.

For describing line-spread functions in general, the half-intensity width, W, is often a useful parameter. In symmetrical functions, W is defined by $B(W/2) = 0\cdot5$ whence, for the fourth-power cosine function :

$$W = 0\cdot3438/F = 1\cdot2872D$$

Taking a medium-speed panchromatic film as an example, it is believed that W might typically be 15μ, whence $F = 23$ lines/mm. and $D = 12\mu$. A fair approximation to the subjective resolving power determined with a high-contrast target is often given by $1/W$; this is 67 lines/mm. in the example.

If the proposed function proves in practice to be a good model, its relation with the well-known $\cos^4\theta$ law of off-axis illumination in an optical imaging system will be of interest. However, whether or not the θ of that law can be identified with the $\tan^{-1}(x/D)$ of the expression for $B(x)$ first given, it may possibly be significant that the distance D appears to be about equal to the emulsion thickness.

Detection of Free Charges from Motor-Car Exhaust Gases

The production of charged entities during combustion is well known[1], and some of these entities have proved to be gaseous ions of low molecular weight containing carbon and hydrogen or oxygen and hydrogen[2]. It is known that ionization takes place in explosion motors and it is used, for example, to detect ignition induced by deposits[3]. Jet aeroplanes are reported to become charged electrically[4]. Part of the charging current (about 500 μamp.) might be due to the preponderance of free charges of a certain sign in the exhaust gases.

In an investigation of the role of unipolar radical ions in radiation chemistry and their radiomimetic properties and possible role in the initiation of lung cancer[5], I have done some preliminary work on the presence of free charges in motor-car exhaust gases and from other sources. The apparatus consisted of a charge collection chamber with a geometry rather similar to that used by Siksna[6] (see Fig. 1). The unit is easily portable (the high-tension device is made with transistors). Careful tests have been done to ensure that creep currents are negligible even under very moist conditions. To this end, the 'Teflon' insulator is heated electrically. The output of the instrument is proportional to the concentration of charge in the gas. In more stationary cases, I have used a large parallel-plate condenser[7] (plate separation distance, 100 mm.; size 300 mm. × 300 mm.) to measure the total current that can be collected, by applying a field-strength of 300 V./cm. This unit measures total rate of production of charge rather than concentration of charge.

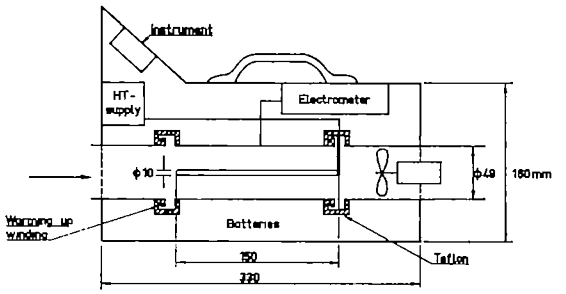

Fig. 1. Portable charge collection apparatus. Air velocity 1 m /sec. Transistorized high-tension variable, 700–1,200 plus or minus. Charge collected at outer electrode is amplified by a conventional electrometer tube circuit. The insulator is heated by mercury batteries. All dimensions are in millimetres

Virtually every car tested (about forty so far) exhibited charge production. On starting the engine, the production is low but increases to high steady states (often ~ 10^7 charges/cm.^{3} at full throttle. The total current collected varies from car to car. In the worst case, a current of 100 μamp. was detected, or more than 10^{14} charges/sec. The positive and the negative parts were nearly equal. In this vehicle, the silencer was in bad condition. Small motors, for example, from 'mopeds', were found to yield rather low currents, namely, about 10^{-9} amp., or slightly more than a cigarette[5]. The charges are confined to the exhaust gas cloud. The concentration drops steadily with distance from the exhaust tube. Nevertheless, I have detected charge concentrations on the pavements of streets with heavy traffic and in the back-seats of cars driving behind Diesel trucks. Starting a car in a garage fills the space rapidly, with a charge concentration which, however, drops in some tens of seconds if the car leaves the garage. The charge monitor is provided with variable collector voltage so that some information on the mobility spectra can be obtained. However, the conditions have not been steady enough to facilitate observations of this kind.

The level of the concentration is roughly the maximum that could be expected from a gas-ion recombination[8], but we are not justified at present in making any exact statements on the nature of the charges detected. There are strong arguments[2] for believing that molecular gaseous ions are produced in explosion motors. The fate of these ions will, however, be dependent on the properties of the exhaust tube, the presence of filters (it is known that wool eliminates most of the ions[9]), the humidity and presence of water or oil droplets, dust, etc. The latter may sorb a large part of the original ions. Further work will have to be done to explore the nature of the charges at different times. It is likely that free radicals can be detected by condensing rapidly the exhaust gases from explosion motors, as is the case for cigarettes[10]. In many other instances, apart from explosion motor exhaust gases, charges have been detected, for example, in gas and electrical welding, smoking of cigarettes and cigars[5], household cooking gas and flames and glowing bodies (such as bread-toasters).

Further study of the nature of these charges would seem to link radiation chemistry and radiation biology with the field of air pollution and public health in an interesting way. If it turns out that the charges represent radiomimetic entities, much can be done to reduce them to low levels, for example, by filtering electrically the inlet and outlet gases in motors.

I am indebted to the Swedish Cancer Society for economic support. Advice by Dr. R. Siksna on the charge collection chamber is also gratefully acknowledged

GEOCHEMISTRY

Apparent Geochemical Association of Bismuth and Thallium

The geochemical association of certain pairs or groups of elements has been noted by several authors, and a classical example is the rubidium/thallium relationship which has been described by Ahrens[1]. In order that such a coherence should be established, it is necessary that not only should a large number of accurate analyses be available but also that these data should be obtained for each element on identical geological specimens.

Until recently, very few data have been available for the abundance of bismuth in silicates due to the lack of analytical methods sufficiently sensitive for its determination at its low concentration levels in such rocks. However, a new method has been developed[1-4] in which this element has been determined spectrochemically after previous enrichment by an anion-exchange procedure. It has also been possible to determine simultaneously thallium and other elements, and abundance data for these two elements have been obtained for some sixty rock specimens. In addition to this work, Ehmann and Huizinga[5] have determined bismuth and thallium at very low concentrations in chondrites by a neutron activation method. The only other simultaneous analytical data for bismuth and thallium in silicates are those of Preuss[6], who estimated these elements by a spectrochemical distillation technique.

I have collated all the available data and noted a surprising apparent relationship between bismuth and thallium, and this is shown in Fig. 1, where a log/log plot of thallium concentrations as a function of bismuth concentration is shown. The points on the diagram for Goldschmidt[7] and the Noddacks[8] are estimates only, and one of my points represents the average of a suite of 19 dolerites from the Jagersfontein diamond mine, South Africa, of which some of the individual analyses show greater scatter than the other points on the graph. All the data include a comprehensive range of silicate rocks from granites to ultra-basics.

The apparent coherence between bismuth and thallium is difficult to explain but it is interesting to note that Oftedal[9] has determined both bismuth and thallium in several samples of galena where both elements are found to be highly concentrated and has reported maxima of 500 p.p.m. thallium and 1,000 p.p.m. bismuth. Goldschmidt[7] has suggested that the enrichment of these metals in lead minerals may be due to the replacement of two atoms of lead by one atom each of bismuth and thallium. The ionic radii of lead, bismuth and thallium are shown in Table 1.

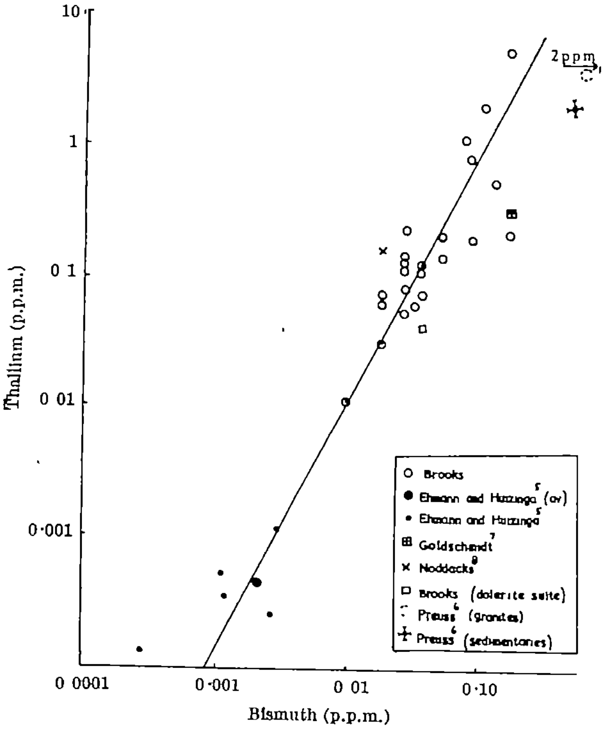

Fig. 1

Table 1. IONIC RADII OF BISMUTH, THALLIUM AND LEAD

Element	Ionic radius
Tl^+	1·49 Å.
Bi^{3+}	1 09 Å.
Pb^{2+}	1 32 Å.

The belief that lead may be the common link between thallium and bismuth is strengthened by consideration of the abundance of lead in silicates[10] where the lead concentration increases regularly from about 3 p.p.m. in ultra-basics to about 20 p.p.m. in granites. It is true that lead is not a major constituent of most rocks ; but since its abundance is very much greater than that of either bismuth or thallium, it is possible that the mechanism of a major element camouflaging a trace element will apply in this case. It is noteworthy that thallium, bismuth and lead are the heaviest three non-radioactive elements, and this may have some significance for their apparent relationship.

Therefore, it may be possible to account for the apparent thallium/bismuth coherence from the premise that one atom each of bismuth and thallium replace two atoms of lead, since the ionic radii of these three elements do not preclude this replacement.

As more data become available for the relative abundances of bismuth and thallium, it should be possible to establish further this apparent relationship.

OCEANOGRAPHY

Overflow of Cold Deep Water across the Iceland–Greenland Ridge

INCREASING attention has been given in recent years to the overflow of cold bottom water, formed by winter cooling in the Norwegian Sea, across the various submarine ridges separating the basin of the Norwegian Sea from that of the Atlantic Ocean. In June 1960, under the auspices of the International Council for the Exploration of the Sea, nine ships from five different countries investigated the overflow across the Iceland–Faroe Ridge by means of a series of parallel hydrographic sections between Iceland

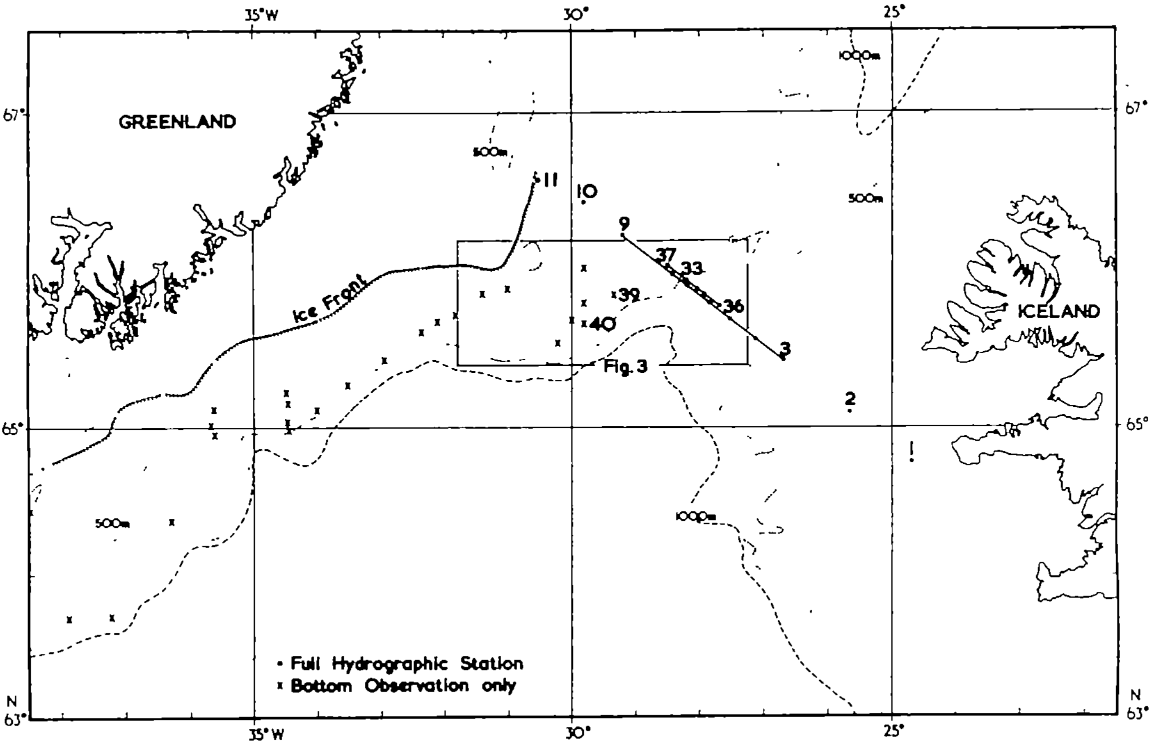

Fig. 1. R.V. *Ernest Holt* Cruise VI 1960 : Location of stations worked in the Denmark Strait

and the Faroes, and made direct current measurements at a number of strategic points.

In August 1960, the English Fishery Research Vessel, *Ernest Holt*, which had participated in the Iceland–Faroe Ridge Survey, worked a hydrographic section across the Denmark Strait (Fig. 1), along the submarine ridge joining Iceland to Greenland, and made direct measurements of the current near the bottom at a selected point along this section. The section was worked on August 15 and 16 from a position some sixteen miles from the Iceland coast to the ice front, approximately eighty miles from the Greenland coast. In the deepest part of the section, that is, below 450 metres, where any overflow taking place would be expected, the coldest bottom water found was 2·5° C. at station 7. Fig. 2*a* shows the central and deepest part of the section.

On the completion of the section, the *Ernest Holt* returned to the position, as near as could be determined, of station 7 to anchor in 550 metres depth (station 33) and make direct measurements of the current near the bottom. It was found that the bottom temperature was now 0·1° C. The time interval between the taking of the bottom temperatures

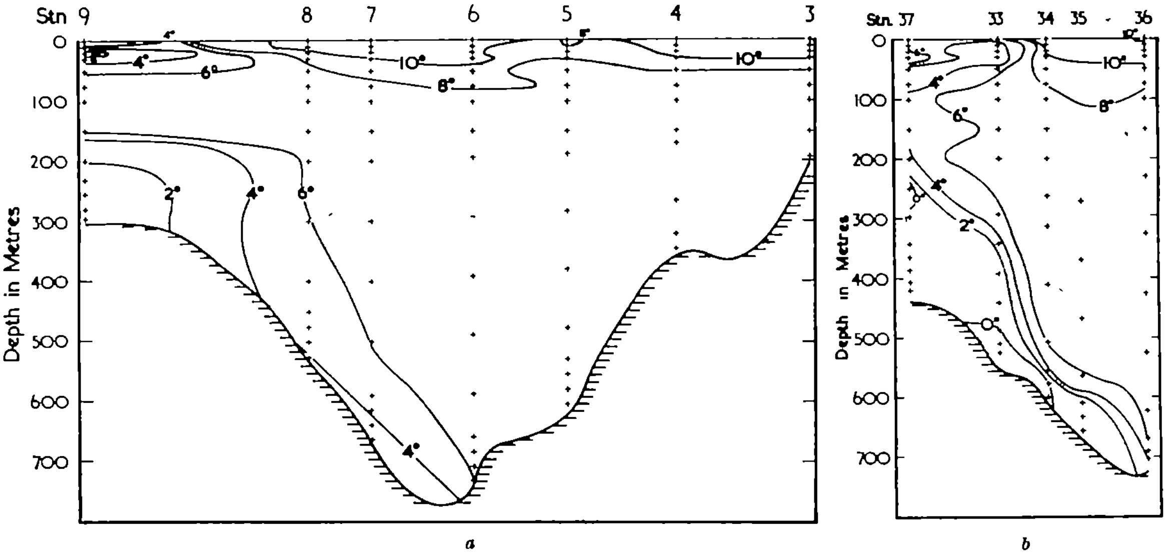

Fig 2. (*a*) Iceland-Greenland Section (1600 hr. G.M.T. August 15–1700 hr. August 16): temperature (°C.). (*b*) Part of Iceland–Greenland Section (1300 hr. G.M.T.–2200 hr. August 17). temperature (°C.)

at stations 7 and 33 was 20 hr. Direct current observations (ten in a period of 14 hr.) were then made within five metres of the bottom by means of a Carruthers' Pisa current indicator[1]. The preliminary analysis of the observations shows a residual current of 0·3 knot in a direction 250° true when the tidal current is eliminated.

Immediately the current observations were completed at 1300 hr. G.M.T. on August 17, the part of the section previously worked in the immediate vicinity of station 7 was repeated in an attempt to delimit the extent of the cold bottom water encountered at station 33 during the measurement of the current. Fig. 2*b* shows the results of this.

After this part of the section had been repeated, a bottom temperature survey on the fishing banks to the west and south of the section was commenced, during which the front of the advancing cold bottom water was identified as lying between stations 39 and 40, sixteen nautical miles apart, at 0430 hr. on August 18, as shown in Fig. 3. The rate of advance of the front of the cold water can be estimated between two limits from the knowledge of the interval of time during which it passed station 7 and the two positions between which it was situated at 0430 hr. on August 18, assuming the axis of flow to have been along the line joining stations 33, 39 and 40. The limits thus determined are 0·55 knot and 1·4 knots, and the line of the axis of flow thus assumed is approximately 255° true. This direction agrees almost exactly with that of the current measured at station 33 and, although both limits of the rate of advance of the cold water front exceed that of the observed current, the lower limit is of the same order of magnitude.

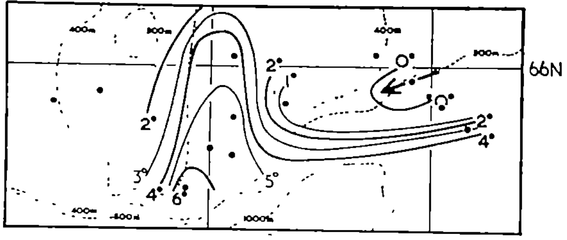

Fig 3. Bottom temperature distribution (° C.) on the south-western side of the Iceland–Greenland Ridge (1300 hr. G.M.T August 17–1600 hr. August 18)
Bottom residual current, ←●—; ●, station

An analysis of the salinity values in the deeper layers of stations 7 and 33 shows the sudden decrease in temperature to be the result of a renewal of the overflow of cold Norwegian Sea deep water across the Iceland–Greenland Ridge. This finding adds support to the hypothesis of Cooper[2] that the overflow is intermittent and takes the form of a series of discrete boluses. It is also in agreement with one of the findings of the Iceland–Faroe Ridge Survey of June 1960, namely, that the bottom temperature on the southern side of these ridges can change rapidly. It is perhaps of significance in a consideration of the factors controlling the overflow that the surface front between the warm Atlantic water and the cold southward-flowing East Greenland Current apparently shifted towards the south-east between the two occasions when the section was worked. As a result of this, on the first occasion when there was little evidence of any overflow, station 7 was located in the warm Atlantic water, but when the *Ernest Holt* returned to station 33 and found a strong overflow it was located in the cold East Greenland Current.

LIMNOLOGY

A Second Lake with Old Sea-Water at its Bottom

FOUR years ago I directed attention to a Lake (Rørholtfjorden, part of Lake Tokke, in southern Norway) with trapped sea-water[1]. The surface altitude of that Lake is 60 m. above sea-level, and the estimated age of its bottom waters some 6,000 years, that is, of the marine salts contained in them ; the present bottom waters probably possessing one-half of the salinity of those originally isolated.

While there are a large number of land-locked waters still having some communication with the sea, there are very few where bottom waters have been completely isolated, and not washed out through admixture with fresh water layers above. Until their discovery in Lake Tokke, salt bottom waters were known only from lakes near sea-level, where isolation through post-glacial land rise must have occurred but recently.

Since my communication, work in progress on Lake Tokke has led to some results, especially concerning isotope distribution in sediments.

Further research made it very desirable to find a second lake with old sea-water, and finally, my collaborator, Mr. H. V. Søvik, in January 1961, discovered such a lake, Botnvatn, in the district of Salten, northern Norway (67° N.), the altitude of the lake surface being 12 m.

Lake Øvrevatn, a land-locked fjord[2] near Botnvatn, with an average height of its water-level of about 2 m. above daily ebb, is at the point of being isolated from the sea. We can thus assume a land rise since the isolation of Botnvatn, of about 10 m., and that the isolation probably took place some 3,000 years ago.

Botnvatn is 113 m. deep, with salt waters from 102 m. downward. Hydrography is very similar to that of Lake Tokke, where salt waters extend from 134 m. to the bottom (147 m.). A comparison may be made between the salt-water layers of the two lakes :

	Tokke, 144 m.	Botnvatn 111 m.
Chlorine (mgm/l)	9 24	7 26
Salinity (gm./kgm.)	16·71	13 14
Temp. (° C.)	5·20	4·75

As is the case in Lake Tokke, the salt bottom waters contain enormous amounts of methane, and bubble violently when brought to the surface. We thus have to face the same problem as in Lake Tokke, that with decrease in pressure the release of methane, also within the sediments, makes it very difficult to secure undisturbed samples of the bottom deposits.

CHEMISTRY

Vibration Frequency and Ionization Potential: Halide Molecules

It has been observed that a systematic correlation is possible between the sum of normal vibration frequencies of a molecule and the first ionization potentials of its constituent atoms.

The sum, $\Sigma\nu$, of all the normal frequencies (degeneracies, if any, included) of a molecule RX_n, where X is a halogen and R a molecular group, has been found to be a linear function of the sum of the first ionization potentials, ΣI_x, of the halogen atoms occurring in the molecule. A plot of $\Sigma\nu$ for a group of molecules with the same R, but with all possible halogen substitutions against ΣI_x, is thus a straight line. Preliminary tests, indicating the validity of the relation, have been made on fifteen CX_4, nine CHX_3, six CH_2X_2, four CH_3X, nine C_2X_4, seven C_2HX_3, five $C_2H_2X_2$, three C_2H_3X, ten $^{11}BX_3$, ten $^{10}BX_3$ and three XCN type molecules.

It is also observed that the $\Sigma\nu$ values of two similar sequences of halides are linearly related:

$$\Sigma\nu(R'X_n) = \alpha\Sigma\nu(RX_n) + \beta$$

provided both the series contain the same number of halogens and the corresponding members are compared.

Details of the work and results of allied investigations will be reported elsewhere.

Delayed Gas Evolution from Passive Films formed in the Kolbe Reaction

During the course of electrochemical kinetic studies on the Kolbe reaction, we have observed a remarkable phenomenon, the details of which are recorded here. The classical Kolbe reaction involves the anodic electrolytic synthesis of hydrocarbons from solutions of salts of appropriate aliphatic carboxylic acids. As a model system for preliminary investigations of the electrochemical kinetics of this reaction, we have examined the anodic reaction which occurs in the electrolysis of a solution of potassium formate in pure anhydrous formic acid; in this case 1 mole of carbon dioxide is evolved in the passage of two Faradays.

During steady-state electrolysis of the above solution at platinum, gold and palladium electrodes, the only gas evolved is carbon dioxide. The overall reaction is hence formally[1]:

$$2HCOO^- \rightarrow HCOOH + CO_2 + 2e$$

On interrupting the current at platinum and gold electrodes, the gas evolution ceases immediately in the normal way. However, on interrupting the current at a palladium electrode, the gas evolution initially ceases, but is then followed by a further burst of gas from the surface after a delay period of up to 5 sec., this gas evolution occurring in the complete absence of current-flow. The effect at palladium is quite reproducible and is best observed at a current density greater than 10^{-1} amp./cm.^{2} in 5-M solutions of potassium formate in formic acid (pre-saturated with carbon dioxide) at 5° C. Although carbon dioxide is evolved at platinum and gold with the same current efficiency (about 90 per cent) as at palladium, the delayed gas evolution is not observed, and the effect hence arises from some property of the palladium anode. No hydrogen is evolved as might be expected by analogy with the coupling reaction occurring with acetic and other aliphatic acids, but this is understandable since any H radicals generated by the anodic decarboxylation will ionize rapidly at a rate of at least 10^{10} amp./cm.^{2} at the high anodic potentials (about 1 2 V. with respect to the hydrogen electrode in the same acid solution) required for significant rates of electrolysis of the formic acid. Hence it is improbable that hydrogen produced in the decarboxylation step and taken up into the surface regions of the palladium is responsible for the effect, and in fact the coulombic yields of carbon dioxide gas by continuous and repeatedly interrupted polarization are identical within experimental error and no hydrogen is detectable by chemical or gas chromatographic means under either set of conditions of polarization.

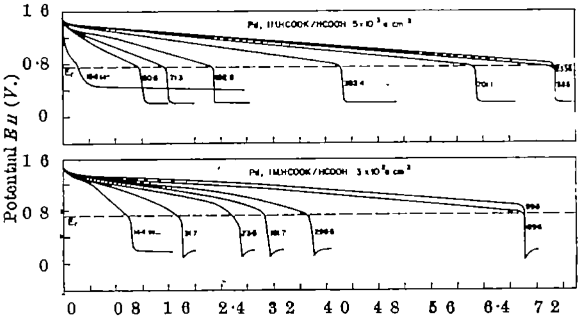

Fig. 1. Open-circuit e.m.f. decay curves taken on an oscilloscope at two current densities of prior polarization for the indicated times (sec.).

Rapid ciné-photography of the palladium surface with a simultaneous recording of the moment when current stops flowing has enabled the delay-times in gas evolution in interrupted polarization experiments to be measured with some precision to about 0·1 sec. The delay-time in the gas evolution after the current stops is found to be a function of the time of previous anodic electrolysis up to periods of about 5 min. This suggests that the anodic electrolysis

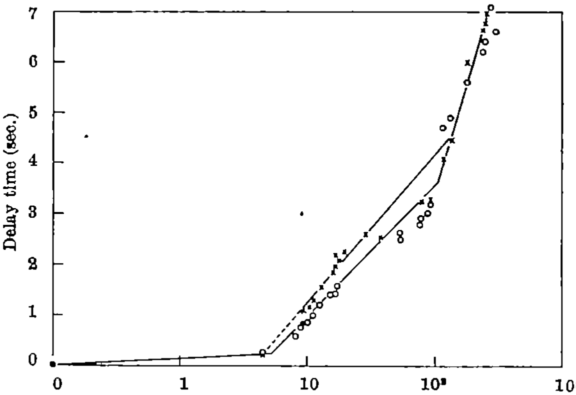

Fig. 2. Relationship of both the delay in open-circuit gas evolution (from ciné photography) and the potential delay to the period of prior anodic polarization at 10^{-1} amp./cm.$^{-2}$. ○, delayed gas evolution, ×, potential delay; 5 M HCOOK/HCOOH

forms a relatively thick film of a surface palladium formate (possibly non-stoichiometric[2,3]) at the electrode, and, after net current ceases to flow, this film breaks down auto-catalytically with evolution of carbon dioxide. The formation of this film appears to be analogous to that of passive films formed anodically, for example, in aqueous solutions at nickel and iron. Determinations of the galvanostatic charging and open-circuit decay curves, using a cathode ray oscilloscope, for the polarized palladium and platinum electrodes indicate the formation of surface films as shown in Fig. 1. The pseudo-capacity associated with the film at palladium is much greater (10–50 times) than that at platinum, and this is evidently the reason why the delayed decomposition is observable at the former metal although it may still occur but not be visible at platinum or gold. We believe that the effect is larger at palladium than at the other metals since palladium is less noble than gold or platinum, so that palladium has a greater susceptibility to anodic oxidation. The delay in the open-circuit decay trace of e.m.f. as a function of time is found to depend on the time of previous anodic polarization, as also observed with the delay in visible gas evolution on open-circuit. The delay in the e.m.f. decay curve, in fact, is directly related to the delay in the open circuit gas evolution as shown in Fig. 2 ; both effects appear to be related to the thickness of the anodically formed layer. Less spectacular self-discharge effects with non-delayed evolution of oxygen occurring over much longer periods of time are known in oxide electrode systems and have been treated in detail in some of our previous papers[2-4]. Visible delayed gas evolution effects are not observed when the true Kolbe coupling reaction is proceeding, for example, in the electrolysis of trifluoroacetic acid, although galvanostatic charging curves again indicate formation of surface films but of thicknesses much less than those found at palladium in the formic acid solutions.

Dielectric and Dipolar Interaction Theories of Solvent-induced Infra-red Frequency Shifts

CONSIDERABLE attention is at present being focused on the effect of solvent environment on infra-red frequencies[1-3]. The early dielectric constant treatment of Kirkwood, Bauer and Magat[4] (KBM), long known to be inadequate for the group frequencies which had been studied in any detail, namely, N—H (ref. 5) and C=O (ref. 6), has been followed by the dipolar association theory of Bellamy, Hallam and Williams[1] (BHW). They have shown that the solvent shift of a range of *X*—H stretching frequencies (where *X* = boron, carbon, nitrogen, oxygen, sulphur, halogens) can be fully accounted for in terms of solute–solvent dipolar interactions and that the bulk dielectric constant of the medium plays an insignificant part. The same theory is also able to explain the major part of the shifts exhibited by *X*=O chromophores[2]. Other factors must, however, have some influence on these dipoles as the slopes of the BHW plots obtained on plotting the relative shifts against a common standard[2] do not parallel other measures of bond polarity as would be predicted on the basis of the dipolar association theory and as has been demonstrated for *X*—H dipoles[1], in particular, N—H (ref. 7). Buckingham's elegant extension of the dielectric theory has been tested and extended by Caldow and Thompson[8] in their detailed evaluation of carbonyl and cyanide shifts. They suggest that both dielectric and specific interaction effects operate, and, by considering interaction terms, based on values of Taft's σ* inductive factors, conclude that the dielectric factor contributes about 30 per cent of the total Δν exhibited by C=O dipoles. Norrish[9] has approached the problem via solute–solution interaction energies in terms of the internal latent heats of solute and solvent and the heat of mixing. However, as he points out, lack of data does not permit a rigorous test of his relationship.

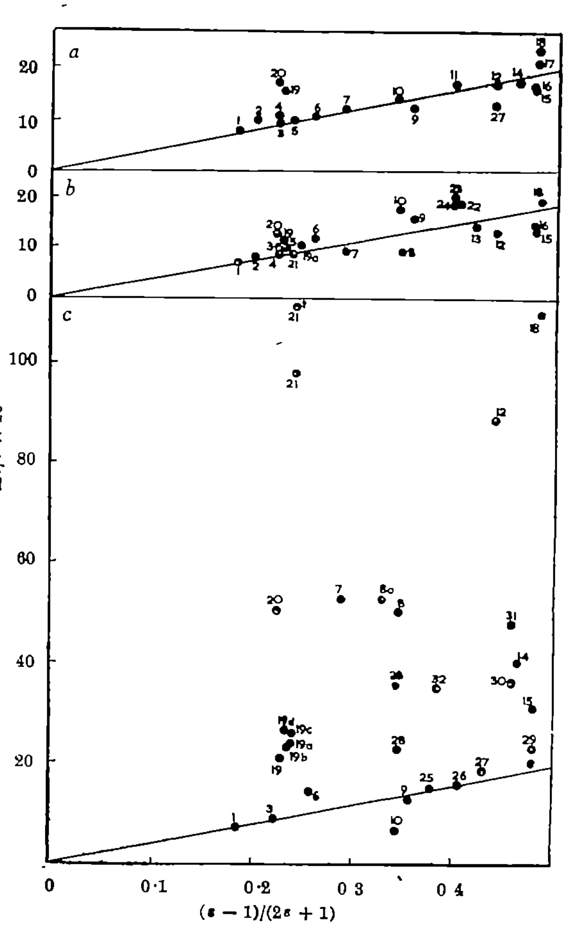

Fig. 1. Relative frequency shift at *a*, ν C—Cl (asym.) of *cis*-dichloroethylene, *b*, ν C=O of acetophenone; *c*, ν N—H of pyrrole in dilute solution as a function of the dielectric constant of the solvent

Solvents: 1, *n*-Hexane; 2, cyclohexane; 3, carbon tetrachloride; 4, cyclohexene; 5, tetrachloroethylene; 6, carbon disulphide; 7, di-*n*-butyl ether; 8, diethyl ether; 8*a*, *iso*propyl ether; 9, chloroform; 10 bromoform; 11, methyl iodide; 12, pyridine; 13, methylene chloride; 14, acetone; 15, acetonitrile; 16, nitromethane; 17, dimethyl formamide; 18, dimethyl sulphoxide; 19, benzene; 19*a*, toluene; 19*b*, *m*-xylene; 19*c*, ψ-cumene; 19*d*, mesitylene; 20, dioxan; 21, triethylamine; 22, pyrrole; 23, aniline; 24, methylene iodide; 25, chlorobenzene; 26, *sym*-tetrachloroethane; 27, 1 : 2 dichloroethane; 28, anisole; 29, nitrobenzene; 30, acetophenone; 31, cyclohexanone; 32, ethyl acetate

We are at present examining the effect of solvent environment on C—halogen frequencies. In general, as might be anticipated for a dipole the end of which most readily available for association is of the same sign, these follow the same overall pattern of solvent behaviour as that exhibited by C=O. The relative shift is also of the same order as for C=O, but a theoretical breakdown of this into the various contributions leads us to the conclusion that with these dipoles the dipolar interaction and dielectric factors play almost equal parts. The most striking outcome is the reasonable success of the KBM treatment, a typical example being shown in Fig. 1*a*, which also includes typical examples of an N—H frequency (Fig. 1*c*), taken from the data of Josien *et al.*[5], and extended by us[1], and a carbonyl frequency (Fig. 1*b*) plotted from the data of Bellamy *et al.*[2], with some additional points from these laboratories. It is immediately apparent that C—halogen KBM plots represent the most satisfactory plots to date of this function. Our analysis in terms of Buckingham's theory[8] as extended by Caldow and Thompson[3] enables us to account for the deviations from the KBM relationship which are found with highly polar solvents such as dimethyl formamide and dimethyl sulphoxide, in terms of specific dipolar interactions.

It is clear that in the development of theories of solvent effects it must be appreciated that neither of the two major factors which contributes to infra-red solvent shifts can be ignored, and that their relative significance varies from case to case, being dependent as much on the particular dipole absorber as on the solvent medium itself.

We are grateful to the Hydrocarbon Research Group of the Institute of Petroleum for financial support and to the Imperial Smelting Corporation, Ltd., for gifts of fluoroform and carbon tetrafluoride.

A New Synthetic Route to Dialkylphosphinous Chlorides

PREPARATIVE methods for dialkylphosphinous chlorides are few in number, and frequently give unsatisfactory yields or require techniques unsuitable for such problems as the synthesis of radioactively labelled compounds of high activity[1-3]. A recently described reaction for the preparation of alkylphosphonous dichlorides[4] has been shown to be adaptable to the preparation of dialkylphosphinous chloride in a single-flask reaction with good yield.

It has been found that alkylphosphonous dichlorides will form a complex with aluminium chloride and an alkyl halide in the same manner as does phosphorus trichloride[5]. Solution of this complex in an electron-donating solvent, for example diethyl phthalate (DEP), followed by reduction with powdered antimony or, preferably, powdered zinc, gives good yields of dialkylphosphinous chloride on distillation.

$$\begin{tikzcd} RCl + R'PCl_2 + AlCl_3 \arrow[r] & {[RR'PCl_2]^+[AlCl_4]^-} \arrow[d, "\text{DEP}"', "\text{Zn or Sb}"] \\ & RR'PCl + [AlCl_3][DEP] + ZnCl_2 \text{ or } SbCl_3 \end{tikzcd}$$

The mixed and symmetrical products prepared by this route are given in Table 1.

Table 1

Compound	b.p /mm.	n^{t}_{d}	Yield (per cent)

BIOCHEMISTRY

Uptake of Deoxyribonucleic Acid (DNA): a Special Property of the Cell Nucleus

ACCORDING to the concept of metabolic stability, DNA is synthesized only before cell division and during the formation of polyploid nuclei. Thus the incorporation of labelled precursors is generally considered to be a measure of DNA synthesis and, consequently, of proliferative activity of the cell population in question.

In the light of recent findings, this assumption does not have absolute validity. Pelc has observed incorporation of adenine-^{14}C and ^{3}H-thymidine into the epithelium of the vesica seminalis in amounts exceeding by 20–80 times the DNA value required for cell division[8,9]. He interprets his findings as metabolic activity of DNA connected with some cellular functions of non-growing differentiated epithelium[10]. In the case of phosphorus, however, no exchange was found in the DNA of single non-dividing cells[5,6].

I have observed DNA labelling in resting cells of bone marrow, thymus and spleen after transfusion of homologous lymphocytes labelled with phosphorus-32. Control experiments using phosphorus-32 as inorganic phosphate were mostly negative, and thus the possibility of metabolic exchange of phosphorus-32 in the DNA molecule itself was excluded[4]. It is therefore assumed that the resting cells of the recipient took up the whole DNA-phosphorus-32 or a large part of it from nuclear debris of injected donor cells.

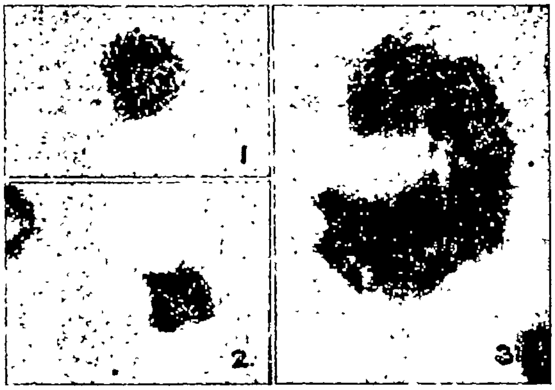

Fig. 1. Autoradiographs of the recipient's bone marrow cells 2 hr. after the application of lymphocytes labelled with phosphorus-32, showing labelling of (1) ring-shaped nucleus of a granulocyte; (2) one segment of the granulocyte nucleus; (3) a megakaryocyte in which the label occurs only in one half of the nucleus. Feulgen, squash. (× 1,725)

The distribution of the label in resting nuclei was examined in greater detail, and the preliminary results are given here.

Homologous lymphocytes labelled with phosphorus-32 were obtained from the thymuses of male *H* mice injected with 25 μc. of inorganic phosphorus-32, 21 hr. before being killed. The thymuses were suspended in isotonic Hanks's solution, the cell suspension was washed and injected intravenously into 10 males of the same mouse strain 24 hr. after total-body irradiation with a dose of 800 r.; X-rays were delivered at the rate of 60 r./min. (180 kV., 15 m.amp., filters 1 mm. aluminium and 0·5 mm. copper, target distance 45 cm.). Each irradiated mouse was given 0·1 mgm. heparin intraperitoneally and 1 ml. of suspension containing 50 million cells with a total radioactivity of 0·01 μc. per ml. The recipients were killed 2 and 6 hr. after the administration of cells. Their bone marrow fixed with acetic alcohol and stained with Feulgen was squashed in accordance with Sachs's method[11]. The non-DNA phosphorus was removed from the preparations by Feulgen acid hydrolysis[6]. The specimens were covered with liquid '*A*-2' emulsion, exposed for 1 month and developed in *D*19.

Labelled cells were found in the bone marrow of the recipients singly and in groups. The Feulgen reaction made possible the differentiation of some cell types only: granulocytes, myelocytes, reticular cells, megakaryocytes, and mononuclear cells of the lymphocyte or erythroblast series. The label occurred in the nuclei of all the types of cell mentioned. In the case of nuclei of small mononuclear cells, the grains of emulsion were evenly distributed. In the granulocytes the distribution of grains was convincing enough to prove radioactivity in the nucleus but not in the cytoplasm (Fig. 1). In some granulocytes only one of the nuclear segments was labelled (Fig. 2). The megakaryocytes often took up the label only in one part of their nucleus (Fig. 3). In the nuclei of the reticular cells, most of the grains were localized above the heterochromatin associated with the nucleolus.

The presence of DNA-phosphorus-32 in the nuclei of granulocytes, which are non-dividing differentiated cells, as well as the accumulation of label only in certain areas of the nuclei of megakaryocytes or reticular cells, exclude the possibility of phosphorus-32 in the form of simpler precursors having been utilized in DNA synthesis and/or in metabolic turnover. The distribution of label in the nuclei gives sufficient evidence that a whole DNA molecule or large portions of it penetrate through certain places on the nuclear surface. Its entrance is probably facilitated by the same mechanisms that are responsible for the penetration of cytoplasmic material giving rise to intranuclear inclusions[7]. The ensuing process of incorporating the DNA which has penetrated into certain nuclear structures remains open to further investigation. In the heterochromatin regions of reticular cells, the label persisted for 48 hr. after the administration of labelled cells[4].

Although it is not possible at present to decide whether incorporated homologous DNA performs its proper biological function, this seems to be the case with autologous DNA. The property of the cell nucleus of taking up DNA from the intercellular environment supports the hypothesis that the lymphocyte nucleic acids are re-utilized by originating cells of the ensuing lymphocyte generation. This has been hitherto based only on indirect biochemical data[1] and cytological findings in lymph node cultures[12] and in spleen lymphoid tissue[2,3].

Prevention of Fatty Liver due to Threonine Deficiency by Moderate Caloric Restriction

Rats fed a diet containing 9 per cent casein supplemented with sulphur-containing amino-acids and choline develop moderately fatty livers, but if the diet is supplemented with threonine, the accumulation of fat is reduced[1,2]. Evidence that fat synthesis is accelerated in rats fed the threonine-deficient diet was obtained by measuring the incorporation of acetate-1-^{14}C into liver and carcass fat[3]. This suggested that rats fed this low protein diet consume an excess of calories in relation to their intake of balanced protein and that the extra calories are used for the synthesis of fat.

The present communication describes observations made on the effect of caloric intake on the production of fatty liver caused by threonine deficiency. A moderate restriction of caloric intake prevented the development of fatty livers in rats fed the threonine-deficient diet, but an equivalent restriction of caloric intake did not prevent the accumulation of liver fat in rats fed a choline-deficient diet.

Male weanling albino rats of the Wistar strain were used. The experiments consisted of two series; in one threonine-deficient diets were fed, in the other choline-deficient diets. The composition of the experimental diets is presented in Table 1. In both series, the control groups of rats were fed the respective basal diets *ad libitum*, and food consumption

Table 1. COMPOSITION OF DIETS

	Threonine-deficient diets			Choline-deficient diets	
	Basal	70 per cent calories	50 per cent calories	Basal	70 per cent calories
Casein	90	90	90	85	85
DL-Methionine	3	3	3	—	—
Sesame oil	50	50	50	50	50
Salt mixture	40	40	40	40	40
Vitamin mixture	4 5	4·5	4·5	4·5	4·5
Choline hydrochloride	1·5	1·5	1·5	—	—
Cholesterol	—	—	—	5	5
Sucrose	815	509	305	815	515
Feed ratio*	1	0 7	0 5	1	0 7

* Relative caloric intakes when diets were fed in quantities that provided equal amounts of protein.

was measured daily. The other groups of rats in each series were fed the same amounts of protein and amino-acids as their respective control groups consumed, but the caloric intakes were 70 or 50 per cent of their respective control groups. At the end of two weeks the rats were killed, their livers were removed and fat was extracted with ether from the dried and finely powdered liver.

As shown in Table 2, the fat content of the livers of the control rats in the threonine-deficient series was 20·3 per cent on a dry weight basis whereas the value for the rats that received 30 per cent less calories was 13·3 per cent, within the normal range. Thus, a moderate reduction in caloric intake with an equal intake of protein prevented the fatty infiltration without appreciably reducing growth. Reduction of caloric intake to 50 per cent of that of the control group further decreased liver fat content (9·2 per cent) but also retarded growth. These results suggest that the balance between amino-acid and caloric intake is important in controlling liver fat accumulation.

Table 2. EFFECT OF CALORIC INTAKE ON FAT CONTENT OF THE LIVERS OF RATS FED ON THREONINE- OR CHOLINE-DEFICIENT DIETS

	Threonine deficiency			Choline deficiency	
	Basal	70 per cent calories	50 per cent calories	Basal	70 per cent calories
Gain for 2 weeks (gm.)	35·5	32 1	16 2	17 0	6 8
Protein intake for 2 weeks (gm.)	11·4	11·4	11·4	8 8	8 8
Caloric intake for 2 weeks	518	363	259	427	299
Liver fat (per cent*)	20·3 ± 3 2†	13 3 ± 0·3	9·2 ± 0 2	30·1 ± 3·6	28·6 ± 4 0

* Liver fat is expressed as percentage of dry liver.
† *S.E.*

This effect was not observed when the fatty liver was caused by choline deficiency (Table 2). The growth of the group fed the choline-deficient diet and 30 per cent less calories than the control group was markedly reduced; however, there was no significant fall in liver fat content. Best and Ridout[4] found that the fatty liver of choline deficiency was prevented by severe, but not by moderate, caloric restriction.

A reduction in caloric intake would decrease the quantity of precursors for fat synthesis. If a fatty liver were caused by an acceleration of fat synthesis due to an excessive carbohydrate intake a reduction in caloric intake would be expected to decrease the fat accumulation. However, if the fatty liver were primarily a result of impaired transport of fat, a reduction in caloric intake would not be expected to affect fat accumulation so much. In this connexion, these results are in agreement with those which indicated that there is an accelerated incorporation of acetate-1-^{14}C into liver fat in threonine-deficient rats[3].

The fatty liver caused by feeding rats a low protein diet that is primarily deficient in threonine appears to be a result of a disproportionately high intake of calories in relation to the intake of balanced protein. This emphasizes the need for further work on the relationship between protein and caloric utilization on animals and subjects having low intakes of protein.

Polypeptide Chains of Hæmoglobin A_2

HÆMOGLOBIN A_2 (Hb-A_2), first described by Kunkel and Wallenius[1], is a minor component found in normal adult hæmolysate which has an electrophoretic mobility slower than Hb-A at alkaline pH. Several variants of Hb-A_2 have been described and these now fall into two groups. While the minor hæmoglobins of one group can occur when Hb-A is normal, for example, Hb-A'_2 (ref. 2) and Hb-B_2 (ref. 3), those of the other group are always associated with α-chain variants of Hb-A. Shooter, Skinner, Garlick and Barnicot[4] described a minor hæmoglobin variant of the latter group which they called Hb-G_2 in an individual carrying Hb-G_{Ibadan}. Since the charge relationship between Hb-G_2 and Hb-$G_{\text{Ib.}}$ was similar to that between Hb-A_2 and Hb-A, Gammack, Huehns, Shooter and Gerald[5] suggested that Hb-G_2 was the naturally occurring hybrid of Hb-A_2 and Hb-$G_{\text{Ib.}}$ This hypothesis implied not only that Hb-$G_{\text{Ib.}}$ has abnormal α_2 sub-units, but also that Hb-A_2 differs from Hb-A only in the composition of the non-α_2 sub-unit and has the molecular formula $\alpha_2^A\delta_2^{A_2}$. It has already been shown[5] that Hb-$G_{\text{Ib.}}$ consists of normal β_2^A and abnormal α_2^G sub-units, and the results now reported are consistent both with the above formula for Hb-A_2 and with the suggestion that Hb-G_2 carries the abnormal sub-unit of Hb-$G_{\text{Ib.}}$ and the specific sub-unit of Hb-A_2.

Hybridization experiments were carried out using a microscale adaptation[5] of the original recombination method developed by Itano and Robinson[6]. Whereas most variants of Hb-A give satisfactory hybrid formation after exposure to pH 4·7 for 4 hr.[7] no new hæmoglobin species could be detected in similar experiments with Hb-A_2. However, if the time of dialysis against acetate buffer at pH 4·7 was extended to 72 hr. or more, amounts of hybrid hæmoglobins sufficient for their detection also formed with Hb-A_2. Thus, when mixtures of the isolated hæmoglobins Hb-A_2 and Hb-G_a were dissociated for these longer

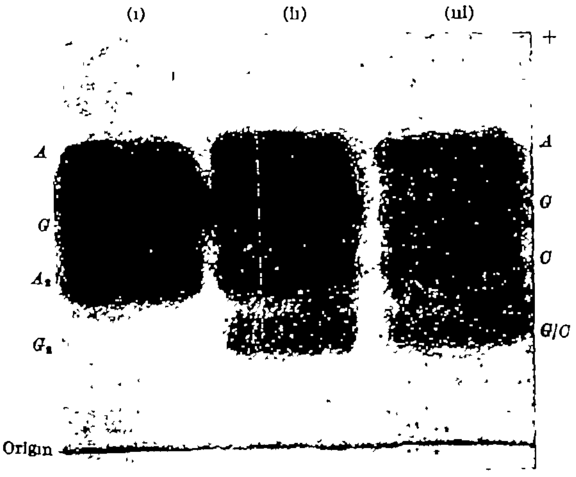

Fig. 1. Hybridization of hæmoglobins A_2 and G_{Br} Starch-gel analysis in the discontinuous system. Migration time 2 hr., *o*-dianisidine stain. (i) Hb-A_2 + Hb-$G_{Br.}$ untreated mixture; (ii) Hb-A_2 + Hb-G_{Br} dissociated at *p*H 4·7 for 96 hr. and then recombined; (iii) Hb-*A*, $G_{Br.}$, *C*, *G*/*C* marker

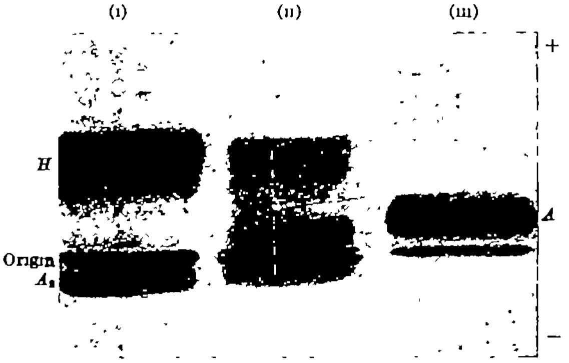

Fig. 2. Hybridization of hæmoglobins A_2 and *H*. Starch-gel analysis in phosphate buffer, gel *p*H 7 4. Migration time 2 hr., *o*-dianisidine stain. (i) Hb-A_2 + Hb-*H* untreated control mixture; (ii) Hb-A_2 + Hb-*H* dissociated for 72 hr. and then recombined; (iii) Hb-*A* marker
(The movement of the new zone (Hb-*A*) in (ii) is slightly decreased by the more concentrated Hb-A_2 zone migrating towards the opposite electrode when compared with the Hb-*A* marker (iii))

periods and then recombined at *p*H 6·8, a new hæmoglobin zone migrating more slowly than Hb-A_2 and in the position of Hb-*G*/*C* appeared and some intensification of the Hb-*A* zone occurred (Fig. 1). With isolated Hb-*H*, Hb-A_2 gave Hb-*A* (Fig. 2). No new species appeared when Hb-A_2, Hb-G_a or Hb-*H* by themselves or a mixture of Hb-A_2 and Hb-*S* were dissociated and recombined in parallel experiments.

The formation of Hb-*A* in the hybridization with Hb-*H* suggests that Hb-A_2 has α_2^A sub-units similar to those found in Hb-*A*.

$$\underset{\text{Hb-}A_2}{\alpha_2^A\delta_2^{A_2}} + \underset{\text{Hb-}H}{\beta_4^A} \rightarrow \underset{\text{Hb-}A}{\alpha_2^A\beta_2^A} + \underset{\text{Hb-}A_2}{\alpha_2^A\delta_2^{A_2}} + (\beta_2^A + \delta_2^{A_2})$$

(The fate of the sub-units enclosed in brackets has not been determined.)

The charge difference between Hb-A_2 and the new hæmoglobin species formed in the dissociation and recombination experiment with Hb-$G_{Br.}$ is similar to that between Hb-*C* and Hb-*G*/*C*. The structural difference between these two is the replacement of the α_2^A sub-unit of Hb-*C* with an α_2^G sub-unit[6]. It therefore follows that the difference between Hb-A_2 and the new hæmoglobin formed in the hydridization experiment with Hb-$G_{Br.}$ could also be the replacement of an α_2^A sub-unit in Hb-A_2 by an α_2^G sub-unit. The reaction may then be written as follows:

$$\underset{\text{Hb-}G}{\alpha_2^G\beta_2^A} + \underset{\text{Hb-}A_2}{\alpha_2^A\delta_2^{A_2}} \longrightarrow \underset{\text{Hb-}A}{\alpha_2^A\beta_2^A} + \underset{\text{Hb-}G}{\alpha_2^G\beta_2^A} + \underset{\text{Hb-}A_2}{\alpha_2^A\delta_2^{A_2}} + \underset{\text{Hb-}G_2}{\alpha_2^G\delta_2^{A_2}}$$

Charge difference
from Hb-*A*:

+ 2 + 4 0 + 2 + 4 + 6

These hybridization experiments are, therefore, consistent with the hypothesis that Hb-A_2 has the general formula $\alpha_2^A\delta_2^{A_2}$.

Raper, Gammack, Huehns and Shooter[8] have suggested from the study of two individuals carrying the four hæmoglobins *A*, $G_{Br.}$, *C* and $G_{Br.}/C$ that the last stage of hæmoglobin synthesis is the combination of α_2 with β_2 sub-units. If this also applies to Hb-A_2, in this instance α_2^A sub-units combining with $\delta_2^{A_2}$ sub-units, then the α_2^A sub-units for the formation of Hb-*A* and Hb-A_2 could be derived from a common pool. It would then follow that an individual who made α_2 sub-units different from those found in Hb-*A* would not only show the corresponding variant of Hb-*A* but also of Hb-A_2. This has been found to be so. In the individual with Hb-*G* disease, who only makes α_2^G sub-units, no Hb-A_2 but a different minor component, Hb-G_2 ($\alpha_2^G\delta_2^{A_2}$), was found[4,5]. Both Hb-A_2 and Hb-G_2 were seen in two unrelated individuals carrying Hb-*A* as well as Hb-G_a (unpublished observations).

It also follows that if the α_2^A sub-units of both Hb-*A* and Hb-A_2 are derived from a common pool, then their formation is controlled at the same genetic locus.

The formation of the other series of Hb-A_2 variants which can occur without any concomitant abnormality of Hb-*A*, such as Hb-A_2' (ref. 2) and Hb-B_2 (ref. 3), indicates that there is a further, separate locus controlling the synthesis of Hb-A_2 and it is suggested that this locus, the δ locus, determines the formation of the $\delta_2^{A_2}$ sub-units. The genotype relevant to the formation of Hb-A_2 in a normal individual would then be α^A/α^A, $\delta^{A_2}/\delta^{A_2}$.

We wish to thank Dr. H. Lehmann for a sample of Hb-G_a trait and for helpful discussions.

Composition of Various Ribonucleic Acid Fractions from Micro-organisms of Different Deoxyribonucleic Acid Composition

THE ratio of guanine plus cytosine to adenine plus thymine (GC/AT) in the deoxyribonucleic acid (DNA) of a given species of a micro-organism is constant, but the GC/AT ratio of different kinds of micro-organisms can vary by a factor of as much as five times[1]. The ratio of GC content to AU (uracil) content of cell ribonucleic acid (RNA) varies only slightly from one organism to another; but this ratio tends to be slightly higher in organisms the DNA ratio of which is high[2]. These facts raise a question as to whether all the RNA of a cell has the same composition or whether perhaps a small RNA sub-fraction has the same base ratios as its corresponding DNA (uracil being equivalent to thymine). Recent experiments have demonstrated an RNA sub-fraction in yeast which does have a composition almost identical to the corresponding DNA (ref. 3). The present work is concerned with analysing the nucleotide ratios in sub-fractions of the RNA from organisms with varying GC/AT ratios in the DNA.

The organisms chosen for this work were *Diplococcus pneumoniae*, in which GC is equal to 38 per cent of total DNA bases; *Escherichia coli*, GC of 50 per cent; and *Micrococcus lysodeikticus*, GC of 72 per cent (ref. 4 and Guild, W. R., personal communication). The organisms were grown in 'Trypticase-soy' medium (Balt. Biol.) at 37° C., with the exception of *D. pneumoniae*, grown in 'Bactotryptose' medium (Difco)[5]. The bacterial growth was collected by centrifugation, suspended in a 0·02 *M tris*(hydroxymethyl)aminomethane buffer containing 0·01 *M* magnesium chloride, and the cells ruptured by passage through a French pressure cell at 5,000 lb. pressure. The resulting suspension was cleared of cell debris by low-speed centrifugation followed by centrifugation at 100,000*g* for 5 min. Deoxyribonuclease was then added to break down DNA to relatively small polynucleotide units. It is impossible for DNA of this size-range to produce significant contamination of any of the final RNA fractions defined here. Three RNA fractions were experimentally defined as follows; a first pellet resulted from centrifuging the cell extracts for 2 hr. at 100,000*g* in a refrigerated Spinco model *L* centrifuge. This pellet should contain all microsomal material of 50*S* sedimentation constant and larger as well as most 30*S* microsomes[6]. A second pellet resulted from centrifuging the supernatant of the previous centrifugation for 5 hr. at 100,000*g*. This should contain mainly material sedimenting with sedimentation constants between 15*S* and 30*S*. For the third fraction, the supernatant of the second fraction was adjusted to *p*H 5 with acetic acid, the resulting precipitate collected by low-speed centrifugation, and redissolved in *p*H 7 buffer. This solution contains the soluble RNA of the cell[7]. Each of the nine fractions defined above was then extracted with water-saturated phenol twice, according to Kirby[8]. Relatively pure RNA was then precipitated by addition of two volumes of cold ethanol, collected by centrifugation, washed again in ethanol, and stored at −20° C. Approximately 10 mgm. of RNA from each fraction was hydrolysed in 1 *N* potassium hydroxide at 35° C. for 18 hr., the potassium ion being afterwards removed by neutralization with perchloric acid. This procedure degraded the RNA to a mixture of 2′- and 3′-nucleotides[9]. The ribonucleotides of the four main bases were separated by paper electrophoresis in a buffer at *p*H 3·6, according to the methods of Markham and Smith[10]. The paper strips containing the nucleotides were afterwards scanned with an ultra-violet lamp ('Mineralight^R') to locate the separate nucleotide bands. Each band was then cut out and eluted overnight in phosphate buffer *p*H 7·5. The ultra-violet absorption spectrum for each nucleotide band was determined in the range 2350–2900 Å. Known mixtures of 2′-, 3′-ribonucleotides were run through the entire hydrolysis procedure in order to determine properly the amounts of each nucleotide present in the RNA hydrolysates. 7–13 electrophoretic runs were made on each fraction. At least two separate hydrolyses by potassium hydroxide of each microsomal RNA fraction occurred. No significant differences in nucleotide ratios between different hydrolyses of the same RNA fraction were observed.

Table 1. NUCLEOTIDE COMPOSITION OF RNA FRACTIONS. *C*, *G*, *U* AND *A* REFER TO CYTIDYLIC, GUANYLIC, URIDYLIC AND ADENYLIC ACIDS RESPECTIVELY

	A	24·7 ± 0·3	24·2 ± 0·4	20·5 ± 0·5
	C + *G*	52·5 ± 1·6	52·4 ± 1·0	56·7 ± 1·4
	U + *A*	47·3 ± 1·9	47·6 ± 0·9	43·0 ± 0·9
	C	20·8 ± 0·4	22·1 ± 0·5	25·1 ± 0·5
	G	33·3 ± 0·8	31·5 ± 1·3	31·7 ± 0·8
M. lysodeikticus	*U*	22·7 ± 0·7	24·1 ± 0·9	23·4 ± 0·5
	A	23·0 ± 0·5	22·2 ± 0·8	19·6 ± 0·5
	C + *G*	54·1 ± 1·2	53·6 ± 1·8	56·8 ± 1·3
	U + *A*	45·7 ± 1·2	46·3 ± 1·2	43·0 ± 1·0

The results are presented in Table 1. The values represent averages of all determinations on a given sample. Errors are presented as probable error. The base ratios for the first RNA fraction of *E. coli* (large microsomes) are the same as those given by Spahr and Tissières for *E. coli* 70*S* microsomes, except for the value of cytosine, which is significantly lower in the present instance[11].

The most obvious result in Table 1 is that none of these RNA fractions has a base ratio approaching that of cell DNA. However, the DNA composition of a given organism does seem to be reflected slightly in the composition of all the RNA fractions. In all three such fractions from each organism there is a statistically significant increase in cytosine and decrease in adenine as the GC content of cell DNA increases. In two of the three cases there is also a significant rise in guanine content, but the results do not give a clear indication of uracil changes as a function of GC content of DNA; a drop in uracil is suggested.

Generally, there is no statistically significant difference between the composition of RNA from small microsomes and that of RNA from larger ones for any given organism. The only exception to this is that in *M. lysodeikticus* cytosine represents a significantly higher per cent of total bases in small microsomes than in large ones. Spahr and Tissières found similarly that the fraction of cytosine in RNA from 30*S* microsomes was significantly higher than that in 50*S* microsomal RNA in *E. coli*[11].

A difference in composition between soluble RNA and microsomal RNA exists. Soluble RNA is significantly higher in cytosine and lower in adenine than is microsomal RNA. However, there is no significant difference in the guanine and uracil composition of the microsomal and soluble RNA's.

In these experiments I have been unable to demonstrate a fraction of cell RNA that has a composition equal to that of its corresponding DNA (assuming uracil to be equivalent to thymine). However, as stated above, such a fraction has been reported for yeast. It seems a possibility then, that all the fractions in the present work are heterogeneous in that they contain a small amount of RNA which has base ratios equivalent to its corresponding DNA, thus producing slight variations in the average base ratios of each fraction in the direction of the base ratios of the corresponding DNA's.

Total Cytochrome Oxidase Activity and its Relation to Basal and Maximal Metabolism

THE study of the values of the basal metabolic rate in mammals and its relation to body-weight has been the object of many papers and reviews since the middle of the nineteenth century. On the other hand, very few data are available concerning the upper limit of animal metabolism; only individual values are found in the literature concerning the maximal metabolism of some mammals and man. The incompleteness of the available data and their suitability for comparative purposes are connected with the difficulty in obtaining the state of maximal performance in animals. In addition, in many of the animals used, maximal oxygen consumption can be obtained only under simultaneous application of work and lowered temperatures, so that the working and thermoregulatory capacity of the animals are used as well. In these conditions, however, a rapid decrease of metabolism occurs as a result of cooling the animals, as I have already shown[1]; it is very difficult, therefore, to find out the period of greatest oxygen consumption. Nearly all the data in the literature seem to be affected by this error, and the results obtained are, therefore, probably lower than true maximal values.

I have looked for other possibilities for a more precise determination of maximal metabolism. It has been found that there exists a constant quantitative relationship among different oxidative enzymes and that the cytochrome oxidase activity readily becomes adapted to various conditions; this suggests that an excess of oxidative enzymes is not present in tissues. It would be expected, therefore, that the maximal possible oxygen consumption of animals and organs will correspond to the terminal oxidative enzyme, the cytochrome oxidase.

I have therefore determined the cytochrome oxidase activity of whole organisms at 37° C. manometrically[3], and the values of oxygen consumption thus obtained have been compared with the values of maximal working metabolism measured in living animals. Before homogenization the animals were depilated, the digestive tract removed and the carcase ground in a meat grinder.

The total cytochrome oxidase activity was determined in six species of rodents (bank vole, field vole, mouse, golden hamster, rat, guinea pig) of body-weight 19–700 gm. It was found that the total cytochrome oxidase activity is proportional to a power of the body-weight, the exponent being very near that found for basal metabolism, namely, 0·67 (Table 1). A similar relationship was also found in various organs and in the musculature of some other mammals[4].

Table 1. AVERAGE CYTOCHROME OXIDASE ACTIVITY IN VARIOUS MAMMALS

Species	Weight of animals without digestive tract (gm.)	Weight of dry substance (gm.)	Cyt. ox. activity (mm.^{3} oxygen/hr./mgm. dry substance)	Total cyt ox. activity (ml. oxygen)	Month
Guinea pig	521·0	202 0	24 1±6·4	4,870	V–VI
Rat	254 0	70 0	24 1±1 7	1,690	III–VI
Golden hamster	64 0	16 8	62 6±3 6	1,050	IX
Mouse	20 6	5 0	62·9±6 7	316	III–IV
Bank vole	17 5	5 4	60 5±8 1	327	IX–XI
Field vole	16·1	5 2	63·0±8·0	327	X

The absolute values of the total cytochrome oxidase activity are found to be very nearly the same as the maximal metabolism of whole animals; the difference does not exceed ± 25 per cent (Table 2). Later experiments have shown that the values of cytochrome oxidase activity measured at 37° C. are not the true maximal values; maximal oxygen consumption is reached at other temperatures, which are different for different animals[4]; this factor may diminish the difference between the values of total cytochrome oxidase and maximum metabolism.

Table 2. COMPARISON OF MAXIMAL METABOLISM VALUES WITH VALUES OF AEROBIC METABOLIC CAPACITY IN VARIOUS MAMMALS

Species	Maximal metabolism (ml. oxygen/hr./gm.)	Cyt. ox. activity (ml. oxygen/hr./gm.)*	Difference (percentage of maximal metabolism)
Golden hamster	13·40	16,40	+ 22
Mouse	17 50	15 35	– 12
Field vole	16 10	20 30	+26
Bank vole	22·40	18·60	– 17

* Cytochrome oxidase activity was measured at 37° C. and referred to 1 gm. of body-weight without digestive tract.

A similar close correspondence between the values of the total cytochrome oxidase activity and maximum oxygen consumption during physical work has been recently found in an insect[6]. Thus this seems to indicate a more general relationship. The methods with which these two values were obtained are, however, so different that they should not be regarded as physiologically identical, and I suggest the term 'aerobic metabolic capacity' for the total activity of cytochrome oxidase, measured manometrically at the optimum temperature and expressed as oxygen consumption, while the values obtained with living animals should be referred to as 'maximal metabolism'.

It seems to me that the determination of the aerobic metabolic capacity may be of value, especially for comparative purposes, as it is readily found and is much more reproducible than the value of maximal metabolism.

A Requirement for 2-Thiouracil of 2-Thiouracil-grown *Escherichia coli* under Conditions of Ornithine Transcarbamylase Repression

PYRIMIDINE analogues may interfere with nucleic acid metabolism by inhibition of the conversion of the free pyrimidine bases to the corresponding nucleotides or by production of abnormal nucleic acids containing substituted pyrimidines. Recently it has been found that an analogue may also function by negative feed-back control and thus inhibit the formation of the normal metabolite[1,2].

This communication describes an additional effect of the uracil analogue 2-thiouracil which was observed under conditions of ornithine transcarbamylase repression. A mutant requiring ornithine, citrulline or arginine (*M*-39 *A*-23) derived from *Escherichia coli* strain *W* was used. 2-Thiouracil was added to cells of this mutant, in logarithmic phase, grown with aeration in minimal medium supplemented with glucose and arginine. As is shown in Fig. 1, a linear increase in optical density with time from 45 to 180 min. is observed. When cells grown for 45–135 min. in the presence of 2-thiouracil were plated on minimal medium supplemented with arginine, up to 90 per cent of the cells lost their ability to form colonies (Fig. 2).

However, when the 2-thiouracil-grown cells were plated on minimal medium containing 2-thiouracil, all the cells were capable of colony formation. It can be seen from Fig. 2 that after pre-incubation periods with 2-thiouracil exceeding 135 min., the proportion of the cell population capable of colony formation on minimal medium without 2-thiouracil increased. Eventually the same colony count was observed on minimal agar plates with or without 2-thiouracil. The transitory nature of the 2-thiouracil

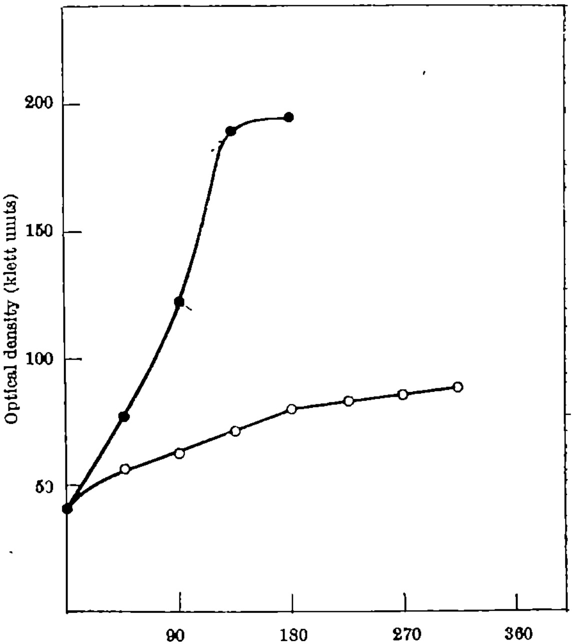

Fig. 1. Growth curve of strain *M*-39 *A*-23 growing in the presence of 20 μgm./ml. arginine with (○) and without (●) 200 μgm./ml. 2-thiouracil

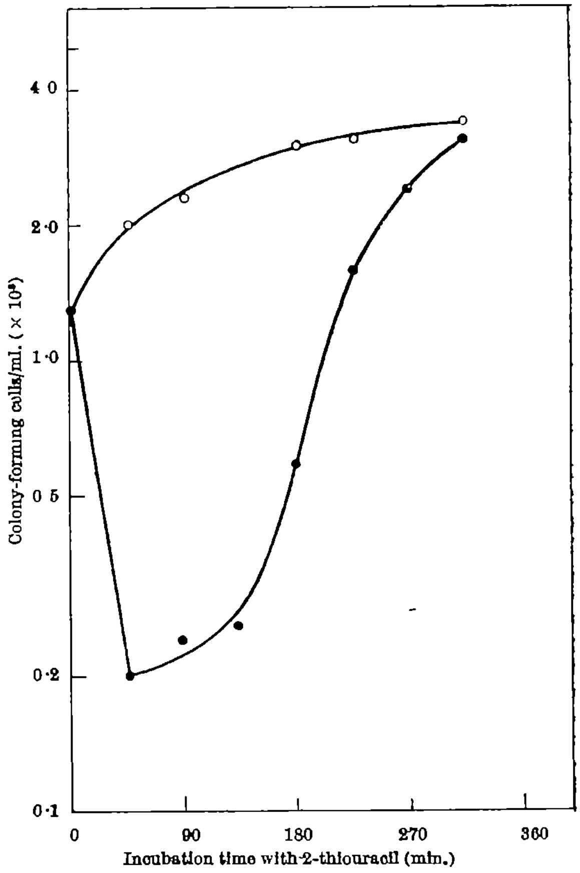

Fig. 2. Colony counts of strain *M*-39 *A*-23 preincubated with 20 μgm./ml. arginine and 200 μgm./ml. 2-thiouracil for the periods indicated, then plated on minimal agar plates with (○) and without (●) 50 μgm./ml. 2-thiouracil

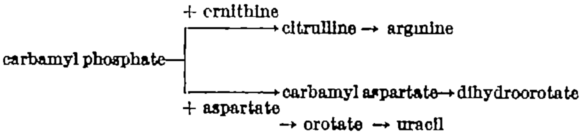
requirement was found to be due to changes in the level of arginine in the pre-incubation medium. Exhaustion of arginine relieved the cells from the 2-thiouracil requirement.

The 2-thiouracil requirement was also obtained when the mutant was grown with 2-thiouracil in the presence of citrulline. However, when the mutant was grown with 2-thiouracil in the presence of ornithine, inhibition of growth was less marked and neither loss of viability nor a 2-thiouracil requirement was observed when these cells were plated on to minimal medium.

Wild-type *E. coli W* cells are only slightly inhibited by 2-thiouracil. However, when arginine was added to the growth medium, 2-thiouracil exerted a marked inhibitory effect and also showed the 2-thiouracil requirement.

In all the experiments described, the 2-thiouracil requirement occurred when the synthesis of ornithine transcarbamylase, which catalyses the conversion of ornithine to citrulline, was repressed. This repression occurs in *E. coli W* and its mutant with arginine or citrulline but not with ornithine. In *E. coli B*, a non-repressible strain[3], no 2-thiouracil requirement was observed under the conditions described.

These results suggest a mechanism based on the metabolic relationship existing between arginine and uracil :



It has been suggested that these syntheses are to some extent competitive[4] and regulated by negative feed-back mechanisms[4,5].

Preliminary results show that 2-thiouracil mimics the feed-back action of uracil. Experiments are now in progress to elucidate the mechanism of the 2-thiouracil effect described.

We are indebted to Dr. B. D. Davis for strain *M*-39 *A*-23 used in this investigation.

A Fatty Acid / Protein Complex in Human Hair

In an earlier publication[1] a new sensitive method for the detection of small amounts of damage to human hair was reported. The method involves counting the numbers of cuticular and cortical cells in the liquid after treating the hair under standard conditions with papain/bisulphite solution. When the ratio of cuticle cells to cortical cells is low, the hair is assumed to have been damaged in some way. Soxhlet extraction of the hair with ethanol increases the rate of breakdown, but ether, benzene and many other non-polar solvents do not affect the ratio. It was suggested that a protective substance soluble in alcohol but not in non-polar solvents exists in the hair which maintains it intact during papain digestion. This protective substance has now been isolated from ethanol extracts and identified as a fatty acid/protein complex.

Isolation by solvent fractionation was impracticable because the materials denatured at liquid/liquid interfaces. Silica fractionation by the method of Hanahan[2] was also unsatisfactory as the material was irreversibly adsorbed on the silica. Successful isolation was achieved by electrophoresis on polyurethane sponge in dilute acetic acid at *p*H 2·5. Under these conditions fatty acids and neutral fatty materials do not move, but the complex moves towards the negative electrode. Analysis of the isolated complex shows that it consists of 20–30 per cent fatty acid and 60–70 per cent protein, which yield substantial amounts of lysine but very little cystine. Methyl esters of the fatty acids are not volatile under normal GLC conditions, but the mass spectrometer indicates there is considerable variation between samples. Treatment of alcohol-extracted hair with an alcoholic solution of the complex reduces the rate of breakdown of hair to the normal level. This is not due to enzyme inactivation, since the degradation of casein by papain is not affected by the presence of the complex. The complex is positively charged in acid solutions and the rate of migration on paper electrophoresis decreases as the *p*H is made more alkaline until no movement is observed at *p*H 6·0. The complex then remains at the origin at *p*H values up to 9·5. This, combined with the high level of lysine, suggests that the fatty acid is combined through the amino-groups of the lysine so that the effective isoelectric point is in the range for normal proteins. In alkaline solution, negatively charged fatty acid residues are removed and this maintains the electrical neutrality of the protein.

PHYSIOLOGY

Distribution of Acetylcholine and Cholinesterase in the Heart of White Rats

THE opinion has been advanced that acetylcholine acts in the heart not only as the mediator of the vagus nerve but also as the so-called local hormone in local extraneural regulation of heart activity and that in this last function it is closely associated with heart automation[1]. If this view is correct, it can be assumed that the most rapid turnover of acetylcholine will occur in those parts of the heart which possess the highest degree of automation. In order to verify the correctness of this assumption, experiments were carried out in which the distribution of acetylcholine and cholinesterase in different parts of white rat heart was examined.

White rats of either sex were used. The animals weighed 190–365 gm. On account of the small amount of tissue available, two animals had to be used for each experiment when the content of acetylcholine was estimated and four animals when the activity of cholinesterase was assayed. The animals were killed by a blow on the head and decapitated. The heart was removed and sectioned as follows: the atria were separated from the ventricles and cut into three parts; the first part represented the region near the opening of the right superior vena cava into the right atrium, the second part the rest of the right atrium with the septum and the third part represented the left atrium; samples of suitable size were removed from the left and right ventricles. The content of acetylcholine bound in heart tissue was estimated by Rothschuh's method[2], employing modifications proposed by Vlk[3]. The activity of cholinesterase was assayed on the basis of the rate of degradation of acetylcholine during incubation of the homogenate of the corresponding part of the heart in a medium containing 200 μgm. acetylcholine chloride per ml. for 30 min. at 38° C. The concentration of acetylcholine was estimated by a chemical method based on the transfer of acetylcholine to the ferric complex of acetohydroxamic acid. Intensity of the red colour was measured with a Coleman spectrophotometer at 540 mμ.

Table 1. CONTENTS OF ACETYLCHOLINE (ACH) AND ACTIVITIES OF CHOLINESTERASE (CHE) IN DIFFERENT PARTS OF WHITE RAT HEART
The figures in brackets represent the number of experiments

Part of the heart	ACh content ± *S.D.*	Activity of ChE ± *S.D.*
The region near the opening of the right superior vena cava into the right atrium	7·07 ± 1·15 (9)	129 ± 8·74 (6)
The rest of the right atrium with septum	5·91 ± 0 94 (9)	114 ± 2·35 (5)
Left atrium	2 16 ± 0·56 (9)	103 ± 2·06 (6)
Right ventricle	—	79 ± 4·86 (6)
Left ventricle	—	71 ± 2 65 (6)

The results are summarized in Table 1. The content of acetylcholine is expressed as μgm./gm. fresh tissue and the activity of cholinesterase as μgm. acetylcholine chloride decomposed by 1 ml. mixture. The content of acetylcholine was determined in the atria only as its distribution in heart ventricles of rats had been known from the paper of Rothschuh[4]. The ventricles are known to contain much less acetylcholine than the atria, the right ventricle having a higher content of acetylcholine than the left one. The highest content of acetylcholine and activity of cholinesterase were detected in the region near the opening of the superior vena cava, whence the levels decrease in the direction of listing the individual parts of the heart in Table 1. The above-mentioned gradient of distribution of acetylcholine and cholinesterase was found in all cases investigated here. The content of acetylcholine decreases much more markedly than the activity of cholinesterase, as shown in Fig. 1, in which the content of acetylcholine and the activity of cholinesterase are expressed as percentage of the basic value which was identified with the value from the opening of the superior vena cava. The right-hand side of Fig. 1 represents the distribution of cholinesterase, the left-hand side the distribution of acetylcholine; the data of the content of acetylcholine in the right and left ventricles were computed from Rothschuh's results[4].

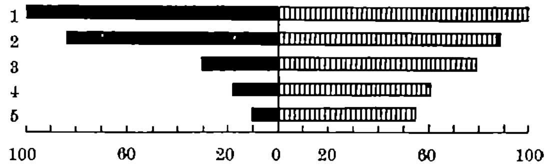

Fig. 1. The distribution of acetylcholine (black) and cholinesterase (shaded) in different parts of white rat heart. 1, Values for the region near the opening of the right superior vena cava in the right atrium; 2, the rest of the right atrium with septum; 3, the left atrium; 4, the right ventricle; 5, the left ventricle

It follows from the results that the highest content of acetylcholine and the highest activity of cholinesterase are to be found in that part of the heart where the rhythmic impulses regulating the automatic activity of the heart are normally generated. This finding is in agreement with the results of Mazel and Holland[5], who found that the most rapid turnover of acetylcholine in poikilothermic animals occurs in the sinus venosus, that is, in the part of the heart which possesses highest automation as assessed from the frequency of contractions of isolated parts. Our results support the view that acetylcholine turnover is of considerable significance in processes which represent the basis of automatic activity of the heart. A detailed report will be published in *Physiologia bohemoslovenia*.

Pharmacological Specificities of Neurones in an Elementary Central Nervous System

RECENT pharmacological investigations by us[1] on the central nervous system of the mollusc *Aplysia depilans* revealed acetylcholine as a possible synaptic transmitter of inhibition. The evidence was obtained by electrophysiological methods; different cells in the abdominal ganglion of this animal were impaled by glass microelectrodes according to previously described techniques[2] and their reactions observed in the presence of different drugs. It was thus shown that externally applied acetylcholine in concentrations up to 10^{-12} hyperpolarizes the membrane and mimics the inhibitory postsynaptic potentials in cells having inhibitory input (conventionally designated as *H*-cells), whereas other cells having only excitatory input (*D*-cells) are depolarized by acetylcholine (Fig. 1*A*). In both cases the impedance of the membrane drops to a low level. The action of acetylcholine on *H*-cells is reversed when the level of polarization of the membrane is increased by artificially applied current. The reversal-level for acetylcholine potentials and inhibitory postsynaptic potentials have equal values, suggesting an identical selective permeability variations of the membrane. In *D*-cells the equilibrium-level is close to the zero membrane potential, indicating a different and non-selective permeability change. Local electrophoretical injections of acetylcholine disclosed a type of response which is identical in synaptic regions as well as in proximal extrasynaptic

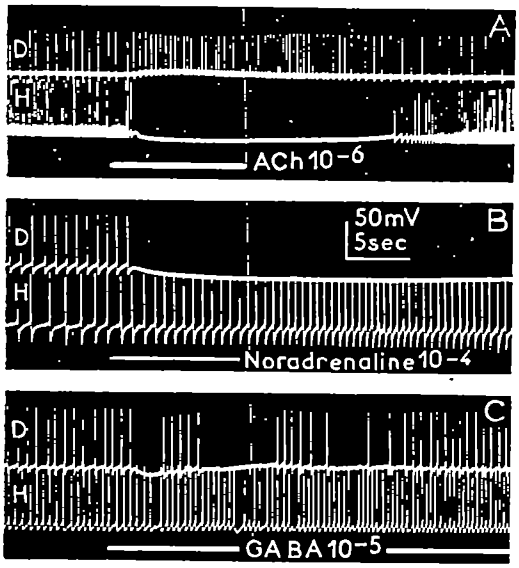

Fig. 1. Action of different drugs (horizontal line) on the spike activity of spontaneous *D* and *H Aplysia* ganglion cells. Simultaneous intracellular recordings from two neurones

membranes ; but the axonal synaptic fields are more sensitive to acetylcholine than the somatic membrane where, as usual in molluscs, there are no synaptic terminals[3]. D-Tubocurarine and atropine in external solutions reduce the inhibitory postsynaptic potentials as well as the action of acetylcholine, whereas eserine first lengthens the inhibitory effect and then reduces the size of inhibitory postsynaptic potentials by inactivating the postsynaptic membrane ; excitatory postsynaptic potentials in *H*-cells are not affected. Consequently, we concluded that the inhibitory synapse in the *Aplysia* central nervous system is cholinergic.

Very striking were the opposite reactions to acetylcholine of contiguous cells ; and it was interesting to see that this specific difference of the two types of neurones appears also with other types of drugs usually considered as having a synaptic action. However, the type of response is different from acetylcholine action. Noradrenaline in solutions up to 10^{-4}, in contrast to acetylcholine, hyperpolarizes and inhibits the *D*-neurones and activates the *H* type (Fig. 1*B*). Adrenaline has the same effect, but is about five times less active than noradrenaline.

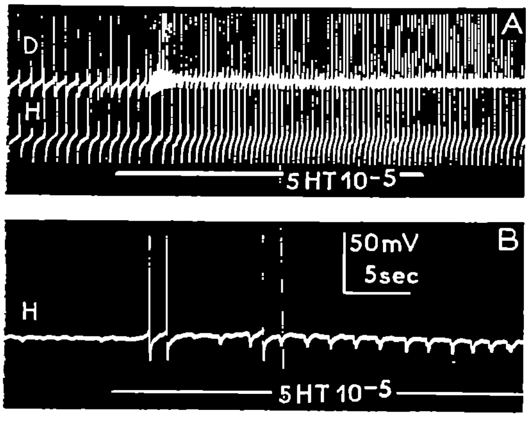

Fig. 2. *A*, Simultaneous intracellular recordings from two spontaneous *Aplysia* cells of different type on application of 5-hydroxytryptamine. *B*, The primary excitatory effect of 5HT on an *H*-cell is masked by inhibitory postsynaptic potentials due to a simultaneous activation by the drug of inhibitory interneurones

γ-Amino-butyric acid (GABA), the participation in inhibitory processes of which was recently discussed[4], usually has a depolarizing and excitatory effect upon the *H*-cells, whereas the *D*-cells, devoid of inhibitory input, are always hyperpolarized and inhibited (Fig. 1*C*). In some cases the *H*-cell is inhibited by GABA ; but this action is not similar to the characteristic transient hyperpolarization provoked by this drug in *D*-cells.

5-Hydroxytryptamine (5HT) excites the two types *H* and *D*, but its effect is more than ten times more intense on *D*-cells (Fig. 2*A*). 5HT is apparently present in the molluscan nervous system[5], and its participation in synaptic transmission has also been considered[6].

When the effect of drugs is studied by perfusing the whole ganglion, the true pattern of response of the membrane to the drug may be changed by the interference of interneurones, which are also affected by the drug. For example, 5HT, the primary action of which is excitatory, can indirectly inhibit an *H*-cell by exciting at the same time an inhibitory interneurone, thus producing inhibitory postsynaptic potentials in the impaled cell (Fig. 2*B*). This may be avoided by injecting the drug locally ; but the perfusion has the advantage of giving additional information about the action of the drug on the interneurone, the activity of which is reproduced in the synaptic pattern recorded in the cell by intracellular electrode. This method enabled us to establish that the inhibitory internuncial neurones, responsible for the inhibitory input on *H*-cells, are of the *D* type.

Conclusions from this work may be summarized as follows :

(1) Two types (*H* and *D*) of neurones with different and specific pharmacological properties are present in the central nervous system of *Aplysia*. These specificities are demonstrated by the response of the *H*- and *D*-cell membranes to acetylcholine, noradrenaline, adrenaline, 5HT and GABA.

(2) The type of pharmacological response is the same on the synaptic and extrasynaptic regions close to the cell body.

(3) The pharmacological pattern of the inhibitory interneurone corresponds to the *D*-type.

(4) These differences in pharmacological specificities of neurones with apparently no special localization in an elementary central nervous system show the difficulties presented by pharmacological studies of neuronal groups and the advantage of concentrating the pharmacological analytical research as much as possible on elementary structures.

Apparent Absence of Amines in Cerebrospinal Fluid of Phenylketonurics

THE mechanism by which mental defect is produced in phenylketonuria is unknown. No correlation has been found in patients having this disorder between the degree of mental defect and blood-levels of phenylalanine or phenylpyruvate, or urinary excretion of phenylalanine, phenyllactate, phenylpyruvate or *o*-hydroxyphenylacetate[1]. The possible implication of biologically active amines has been examined in several papers. Mitoma *et al.*[2] administered *o*-tyrosine and *m*-tyrosine to experimental animals and observed conversion to the corresponding amines in brain, with attendant central nervous system stimulation and convulsions. Association of the mental defect in phenylketonuria with an excessive production of *o*-tyramine was suggested. It also seems possible that overproduction of phenylethylamine may be responsible for the disturbance in cerebral metabolism. Jepson *et al.*[3] have recently shown that administration of a monoamine oxidase inhibitor to phenylketonuric individuals results in an increase much greater than normal in the urinary excretion of phenylethylamine, but not of *o*-tyramine. The mental defect in phenylketonuria may also be due to an underproduction of amines vital to normal brain function. Pare *et al.*[4] have reported low serum serotonin-levels and decreased urinary excretion of 5-hydroxyindoleacetic acid in phenylketonuria. They suggest that one or more aromatic acid metabolites of phenylalanine inhibit 5-hydroxytryptophan decarboxylase, the enzyme responsible for the production of serotonin.

It was felt that the demonstration of the presence or absence of biologically active amines in cerebrospinal fluid might give clues to the mechanism of the mental defect in phenylketonuria. Because cerebrospinal fluid is formed in the ventricles and bathes the brain, it may be in a better position than other body fluids to reflect the biochemical changes occurring in the brain in disease. In the recently discovered disorder argininosuccinicaciduria[5], the concentration of argininosuccinic acid has been found to be greater in cerebrospinal fluid than in plasma, and may reflect a derangement in cerebral metabolism.

In the present work, 4 phenylketonuric children and 4 control children of similar ages having mongolism were given orally a potent monoamine oxidase inhibitor, β-phenyl*iso*propylhydrazine ('Catron', *JB*–516), in a dosage of 9–12 mgm. once daily for 12–14 days. Before and again after 12–14 days of monoamine oxidase blockade, 10 ml. of cerebrospinal fluid was obtained from each patient by lumbar puncture. Cerebrospinal fluid was stored at − 20° C. until used. None of the patients exhibited any consistent change in behaviour while receiving 'Catron', other than that expected incident to the discomfort of removing cerebrospinal fluid.

Specimens of cerebrospinal fluid were deproteinized by ultrafiltration at 5° C. for 24–36 hr. Amines were absorbed on the resin 'Amberlite *CG*-50', type 2 (H^+ form) according to the method of Awapara *et al.*[6]. Each filtrate of cerebrospinal fluid was shaken for 1 hr. with 1 gm. of resin on a mechanical shaker, the resin was washed with water in a column, and the bases were then eluted with 4 *N* acetic acid. The eluate was lyophilized, and the residue was dissolved in 0·5 ml. of 10 per cent aqueous 2-propanol.

The concentrates of cerebrospinal fluid were chromatographed one-dimensionally on Whatman No. 1 paper in butanol/acetic acid/water (12 : 3 : 5). The equivalent of 1 ml. of original cerebrospinal fluid was applied to each chromatogram. Individual chromatograms were prepared from each specimen for development with ninhydrin, diazotized *p*-nitroaniline, and *p*-dimethylaminocinnamaldehyde. As little as 0·05 μgm. of serotonin, 0·25 μgm. of *o*-tyramine and 0·25 μgm. of phenylethylamine could be detected readily. Graded amounts of these authentic amines were chromatographed simultaneously on the same sheet with each specimen of cerebrospinal fluid.

No amines were detected in 1 ml. of cerebrospinal fluid from each of the 4 phenylketonuric and 4 mongoloid patients, either before or during monoamine oxidase blockade. The unused portions of concentrates of cerebrospinal fluid obtained during monoamine oxidase blockade were then pooled, and most of the salts and basic amino-acids were removed by precipitation with ethanol and acetone according to the technique of Rodnight[7]. Again, no amines were detected on chromatograms prepared from 10 ml. of pooled phenylketonuric or pooled mongoloid cerebrospinal fluid.

The efficiency of the recovery procedure for amines in cerebrospinal fluid and the possibility that amines might be destroyed during deproteinization by monoamine oxidase naturally present in the cerebrospinal fluid were checked by adding authentic amines to cerebrospinal fluid. 2 μgm. of serotonin and 10 μgm. of phenylethylamine per ml. were added to cerebrospinal fluid obtained from phenylketonuric and mongoloid patients prior to monoamine oxidase blockade. The cerebrospinal fluid specimens were incubated for 4 hr. at 37° C. to promote possible enzymatic action, and then were deproteinized by ultrafiltration for 36 hr. at 5° C. The filtrates were processed and chromatographed as previously described. Recoveries of added serotonin and phenylethylamine were about 75 per cent.

The results show that cerebrospinal fluid of each phenylketonuric patient during monoamine oxidase blockade contained less than 0·05 μgm. of serotonin and less than 0·25 μgm. of phenylethylamine and *o*-tyramine per ml., and that pooled phenylketonuric cerebrospinal fluid contained less than 0·005 and 0·025 μgm. per ml. respectively of these amines.

The failure to detect amines in phenylketonuric and mongoloid cerebrospinal fluid during monoamine oxidase blockade may be due to insufficient sensitivity of the technique used. Published reports suggest that the concentration of amines in cerebrospinal fluid is very low, if indeed they are present at all. Sachs[8], using a biological assay method, found serotonin in cerebrospinal fluid of some patients with head injuries and brain tumours. It is possible, however, that this serotonin may have been derived from bleeding into the subarachnoid space. Weil-Malherbe and Liddell[9] determined epinephrine and norepinephrine fluorimetrically in cerebrospinal fluid, and found these amines present in average concentrations of 0·9 and 2·8 μgm./l. respectively. The possibility that, in the present experiment, amines originally present in the cerebrospinal fluid in low concentration were destroyed enzymatically has not been excluded, but this seems unlikely since the patients were given a potent monoamine oxidase inhibitor, and in view of the recovery of added authentic amines after incubation of cerebrospinal fluid.

It is likely that many intracellular biochemical alterations in the brain are not reflected in the cerebrospinal fluid. For example, γ-aminobutyric acid, present in relatively large amounts in the brain and the retina but not elsewhere in the body, is not normally found in cerebrospinal fluid. A failure to find amines in cerebrospinal fluid, even during monoamine oxidase blockade, may result simply from inability of these substances to penetrate from the brain or blood into the cerebrospinal fluid. Thus the results of the present work do not exclude the possibility that the mental defect in phenylketonuria may be related to an underproduction of serotonin, or an over-production of phenylethylamine or *o*-tyramine.

Dynamics of Renal Proximal Tubular Secretion

A NUMBER of exogenous substances such as penicillin, 'Diodrast' and *p*-aminohippuric acid (PAH) are secreted in the proximal tubules. Nothing definitely is known about the mechanism of uptake of these substances in the tubular cells and further transport into the tubular lumen[1]. It is likely that enzymatic reactions are involved so that PAH reacts with an enzyme (carrier) in the cell membrane since the kidney cells seem to be impermeable to it. The concentration of PAH therefore approaches zero in the vicinity of the cell. However, it must traverse the wall of the capillary and the interstitial water before reaching the tubular cell. This probably takes place as diffusion along a concentration gradient. The concentration of PAH in the capillary plasma will therefore never be zero.

It is, however, not reasonable to explain in this way extraction of PAH (E) as low as 0·90 or lower at low plasma concentrations since similar extractions have been found for PAH and 'Diodrast' although these substances have very different diffusion coefficients[2]. When the flow of blood through the kidney is increased at unchanged arterial hæmatocrit, the extraction of PAH is considerably reduced (ref. 3 and unpublished work).

When blood with a low plasma concentration of PAH (c_0) reaches the glomeruli, fluid is filtered off, whereas the plasma concentration remains essentially unchanged. During the passage of the postglomerular capillaries the PAH concentration is reduced to $c_0(1 - E)$. The total amount removed and secreted into the tubular fluid is the sum of the amounts abstracted at all levels of the capillaries with decreasing concentration of plasma.

It is well known that the reaction velocity of enzymatic reactions, in this case the reaction which limits the transport-rate for PAH from interstitial fluid into tubular fluid, depends on the concentration of the substrate. The reaction velocity is low at low concentrations and increases to a maximum (V) which is uninfluenced by further increase in the concentration of PAH (c) delivered to the tubular cells. The relationship between reaction velocity and concentration of substrate is expressed in Michaelis's equation[4]:

$$v = Vc/(c + K_m) \qquad (1)$$

K_m is the Michaelis constant (the concentration of substrate at which the reaction proceeds at half the maximal velocity) and v is the amount of PAH abstracted from the capillaries per unit length and unit time. Since the concentration of PAH is decreasing during the passage of the capillary, it follows that:

$$v = -\mathrm{d}c/\mathrm{d}t \qquad (2)$$

where t is the time of passage through the capillary.

By combination of these two equations and integration for the time t between the limits for PAH concentration c_0 and $c_0(1 - E)$:

$$E + \ln(1/1 - E)K_m/c_0 = Vt/c_0 \qquad (3)$$

The rate of flow of plasma through the capillaries is inversely proportional to the passage time when the volume of the capillaries remains constant. The equation may therefore be rewritten:

$$E + K_m \ln(1/1 - E)/c_0 = K_0 f \qquad (4)$$

where K_0 is a constant and f is the flow-rate.

Maximal extraction values for PAH are obtained when its concentration is low (lower than K_m). The ratio K_m/c_0 is therefore larger than unity.

Fig. 1 shows that the extraction of PAH is reduced when the renal plasma flow-rate through the postglomerular capillaries is increased. The relationship between E and percentage increase of flow of plasma is in good accordance with experimental findings (unpublished). The basis for Fig. 1 is the assumption that the extraction is 0·8 at a renal plasma-flow of 200 ml./min. It is evident from the figure that the values for extraction of PAH at a given flow-rate are nearly identical whether the arterial plasma concentration for PAH is twice (filled circles) or ten times (open circles) smaller than K_m. This deduction is also in accordance with experimental findings.

This hypothesis explains why the extraction of PAH may be reduced without a similar reduction in Tm for PAH. At high plasma concentrations the amount removed will not vary with blood-flow. This can be shown by integrating the Michaelis equation with respect to capillary volume. The result is:

$$T - fK_m \ln(1 - T/fc_0) = K_1 \qquad (5)$$

where T is the total amount secreted per minute and K_1 is a constant. When the load of PAH ($fc_0 = L$) delivered to the tubular cells is large compared with the amount secreted, the second term in equation (5) vanishes, and T reaches its maximal value, usually called Tm. In titration curves for PAH the relation-

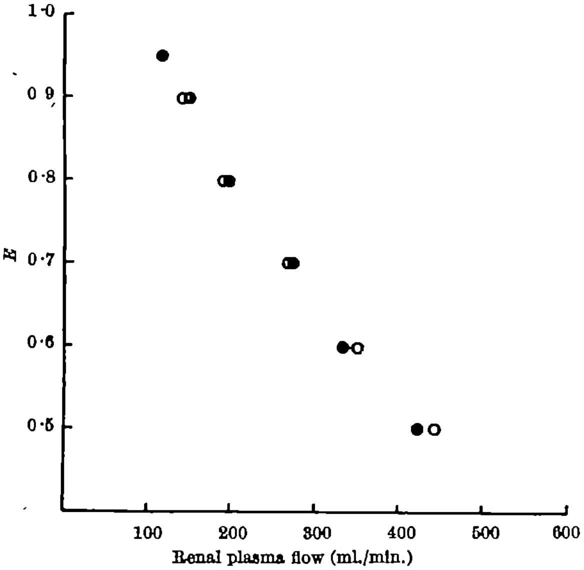

Fig. 1. Expected extraction of PAH at various rates of flow of plasma. ●, when $K_m/c_e = 2$; ○, when $K_m/c_e = 10$

ship between T/Tm and L/Tm is shown. The equation (5) may therefore be rewritten :

$$T/Tm - K_2 \log(1 - (T/T_m/L/T_m)) = 1 \qquad (6)$$

where K_2 is a constant when plasma flow is constant.

Fig. 2 shows the results for PAH-titration of a 53-year-old normal man[6], and the stippled curve is the titration curve for PAH as interpreted by Smith[6].

The other curve is plotted on the basis of equation (6), assuming $T/Tm = 0{\cdot}75$ and $L/Tm = 1$ as reference point. The shape of the curve obviously depends on this choice, and curves which fit the experimental data better may be found. According to equation (6) the tubular transport system is 90 per cent saturated when the load is slightly more than twice Tm, but 95 per cent saturation requires a load more than eight times larger than Tm. Tm is never reached, but only approached. As apparent from Fig. 2, Smith's and my estimates of Tm are different. The common assumption that there is no splay in the titration curve of an individual nephron obviously has to be reconsidered.

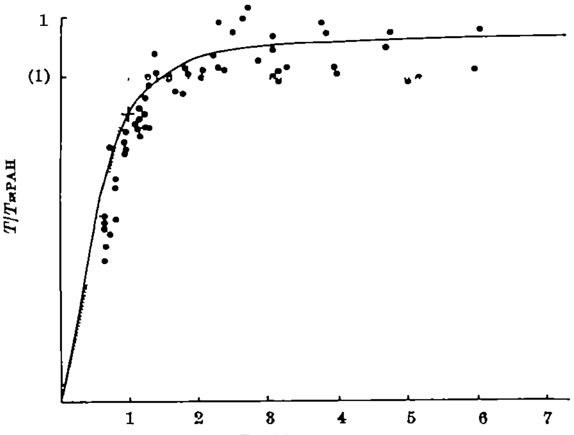

Fig. 2. PAH titration curve redrawn after H. Smith (ref. 6, 166). Solid line shows titration curve if Michaelis's equation is followed

A similar reasoning may be used for reabsorptive processes with a maximal reabsorptive capacity, but is more complicated since the decrease in concentration of the substrate during the passage of the proximal tubules is not only a function of the rate of reabsorption of the substrate but also a function of the considerable rate of water abstraction.

The model proposed suggests that the rate-limiting process for the transport of PAH follows Michaelis equation. This process is not necessarily localized in the cell membrane towards the tissue side, but evidently is a function of the substrate concentration in the interstitial fluid. The maximal rate of transport may therefore depend on the concentration of enzyme for the rate-limiting reaction. Competitive inhibition of transport processes may be interpreted along these lines. By means of titration curves for chemical analogues the constants V and Km in Michaelis's equation may be evaluated. The rate-limiting process may, however, not be the same for transport of different analogues.

Minimum Rates of Flow in Therapy with Sulphonamides

Recent work on the kinetics of the acetylation of sulphisoxazole[1] and sulphamethylthiadiazole[2] in human beings indicate that excretion of acetylated drug is the terminal step in a two-step consecutive first-order process the first step of which is acetylation. This kinetic model was tested for ability to describe the metabolism and excretion of sulphathiazole taken by normal adult humans under a standard test procedure[1]. When 0 5-gm. doses were taken, excretion of acetylated drug was well described by the appropriate mathematical expression[1,2]. However, when one subject took a 1·0-gm. dose, it was not possible to describe the excretion of acetylated sulphathiazole by the same expression. The test was repeated with the same subject about two weeks later, and a water intake of about 500 ml./hr. maintained during the first 8 hr. of the test. This time excretion of the acetylated drug was well described by the expression. Using the rate constants obtained in the second test to calculate maximum excretion-rate of acetylated sulphathiazole by this subject from a 1·0-gm. dose, and comparison of this rate with the average urine flow-rate during the expected time of occurrence of the maximum during the first test, indicated that the solubility of acetylated sulphathiazole was exceeded at the average urine pH. It seemed reasonable to believe that crystalluria had occurred during the first test with a 1·0-gm. dose which would prevent description of excretion by the expression previously found to hold when a smaller dose was taken. There was no evidence of hæmaturia on casual gross examination of the urine specimens obtained in the first test with a 1·0-gm. dose.

The fact that the excretion of at least three acetylated sulphonamides[1-2] can be described in terms of several rate constants allows the following generalization to be made concerning minimum rate of flow of urine needed in therapy with these sulphonamides in order to prevent crystalluria.

Urine concentration of acetylated drug is given by:

$$Cu = \frac{dSae}{dt}\Big/\frac{dU}{dt} \qquad (1)$$

where Cu is the concentration in mgm./ml., $dSae/dt$ excretion-rate of acetylated drug in mgm./hr. and dU/dt average rate of flow of urine in ml./hr. It is usual in therapy to give an initial loading dose of drug, followed by maintenance doses at regularly spaced intervals. This procedure establishes blood-concentration and body-level at a nearly constant value. Excretion-rate of acetylated drug is given by:

$$\frac{dSae}{dt} = k_2Sa \qquad (2)$$

where k_2 is the first-order rate constant for excretion of acetylated drug in reciprocal hours and Sa is the amount of acetylated drug in the body at any time in mgm. The rate of change of acetylated drug in the body with time is:

$$\frac{dSa}{dt} = k_1g - k_2Sa \qquad (3)$$

where k_1 is the first-order rate constant for acetylation in reciprocal hours, and g is the constant amount in the body in mgm. For simplicity in mathematical treatment, it is assumed that the dose is instantaneously absorbed and equilibrium in body fluid is immediately obtained.

Equation 3 may be integrated and constant evaluated at zero time to obtain:

$$Sa = \frac{k_1g}{k_2}(1 - \exp[-k_2t]) \qquad (4)$$

Equation 4 reduces to the following at a time infinite in terms of the experiment:

$$Sa = \frac{k_1g}{k_2} \qquad (5)$$

It can be calculated on the basis of data available for the mean value of k_2 for sulphisoxazole[1] that equation 4 is within 95 per cent of the value given by equation 5 in 40 hr.; with sulphamethylthiadiazole[2] in 4 hr., and with sulphathiazole (unpublished work) in about 8 hr. Substituting equation 5 in equation 2 gives:

$$\frac{dSae}{dt} = k_1g \qquad (6)$$

Substituting equation 6 in equation 1 and rearranging gives equation 7:

$$\frac{dU}{dt} = \frac{k_1g}{Cu} \qquad (7)$$

If Cu in equation 7 is taken as the solubility of the acetylated sulphonamide at a given urine pH, then dU/dt becomes the minimum rate of flow of urine needed to prevent the occurrence of crystalluria.

Table 1. MINIMUM URINE-RATES OF FLOW (ML./HR.)

Urine pH	Sulphisoxazole	Sulphamethylthiadiazole	Sulphathiazole
5·0	190	90	420
5·5	60	60	400
6·0	20	40	370
6·5	10	20	280
7·0	5	10	170

Some calculations made with equation 7 are listed in Table 1. Solubility was calculated as a function of urine pH by the procedure of Krebs and Speakman[3] for sulphathiazole. Values for solubility of acetylated sulphisoxazole and acetylated sulphamethylthiadiazole at the several pH's were obtained from published values[4]. The mean value of k_1 used in each case was obtained from the work previously mentioned[1-2]. The value of g was taken as 1 gm. and, from equation 7, flow-rate is directly proportional to this quantity.

Calculation of minimum values of rate of flow assumes no supersaturation of urine can occur, and that precipitation is immediate when solubility is exceeded.

HÆMATOLOGY

Reduced Fibrinolytic Activity of Atherosclerotic Sera caused by an Increase in Low-density Lipoproteins in Blood

RECENT work from several laboratories indicates abnormalities in bloods of atherosclerotic patients characterized by high cholesterol-level, elevation of cholesterol : phospholipid ratio and elevated low-density lipoproteins[1-3]. These abnormalities are reflected in a remarkably poor fibrinolytic activity of these bloods[4]. The work reported here was carried out in an attempt to find out the cause of low fibrinolytic activity of such bloods (collected from patients with advanced atherosclerosis), and to determine the nature of the material responsible for the inhibition. It is also hoped that such studies will enable us to find out the cause of frequent coronary deaths among older people after they have had fatty evening meals. The present work was based on analyses of blood specimens obtained from patients having a history of myocardial infarction, in the belief that these patients had developed atherosclerosis.

Blood samples collected from normal individuals (without known vascular or cardiac disease) between 30 and 40 years of age and from those with a history of coronary infarction were tested for fibrinolytic activity. The ability to dissolve a fibrin clot was used to measure the fibrinolytic activity of these blood sera. To each specimen an equal volume of highly purified fibrinogen[5] was added, mixed well and then thrombin was added to the mixture to produce clotting. The concentration of fibrinogen in the final solution was 0·2 per cent. Fibrinolytic activity was also measured in some cases after activation of the serum with streptokinase[6]. In general, the fibrinolytic activity of normal serum has always been found to be

Table 1. FIBRINOLYTIC ACTIVITY OF SERA

Normals			Atherosclerotics		
No.	Age	Percentage of clot lysis in 24 hr.	No.	Age	Percentage of clot lysis in 24 hr.

9	38	100	9	62	70
10	37	82	10	67	64

30–35 per cent higher than the corresponding values for sera collected from atherosclerotic patients (Table 1).

Chylomicra and low-density lipoproteins were removed from the sera with a Spinco model *L* preparative ultracentrifuge according to the method developed by Havel *et al.*[7].

The removal of chylomicra and low-density lipoproteins from the blood of atherosclerotic patients results in an increase in fibrinolytic activity (Table 2). The subsequent removal of α-lipoproteins from these blood samples does not alter their fibrinolytic activities. The removal of low-density lipoproteins thus renders these blood samples indistinguishable from normal bloods which have also been subjected to similar treatment.

Table 2. FIBRINOLYTIC ACTIVITY OF SERA BEFORE AND AFTER TREATMENT

8	32	75	100	8	66	38	90

* Serum was either treated with chloroform/methanol mixture or subjected to the method of Havel *et al.* in order to remove chylomicra and low-density lipoproteins.

Repeated treatments (5–6 extractions) of normal serum or serum obtained from atherosclerotic patients' blood with chloroform–methanol mixture (1 : 1 by volume), which removes chiefly the low-density lipoproteins, tends to raise the fibrinolytic activity of the atherosclerotic patients' blood to the value of the normal blood after similar treatments, although originally the fibrinolytic activities of those samples had been different (Table 2). These findings are in good agreement with those reported by Greig and Runde some years ago[4]. Similar treatments of the plasma with petroleum ether (b.p. 40–60° C.), which renders the plasma unclottable by Russell's viper venom and calcium[8,9], fail to alter the fibrinolytic activity of these blood samples. The poor fibrinolytic activity of the circulating blood can thus be attributed to the presence of low-density lipoproteins rather than any free phosphatides. Another point of interest is the fact that phospholipids extracted from the serum by the use of a chloroform–methanol mixture cannot inhibit fibrinolysis, at least not at the physiological concentration-level, since streptokinase-activated plasminogen (streptokinase and human serum) requires almost as much time to dissolve a fibrin clot in the presence of phospholipids as in the absence of this material.

Since 1940, it has been known that blood, after repeated treatments with chloroform, becomes fibrinolytic ; but it is not known what factor or factors (that can be removed by chloroform–methanol mixture) act as inhibitors of the fibrinolytic system of the circulating blood. One possible explanation might be that they form some type of inert complex with either plasmin or plasminogen, thereby preventing the former from acting on its substrate (fibrin clot) or the latter (plasminogen) from being spontaneously converted to plasmin. The fact that chloroform–methanol mixture can remove the factor or factors, acting as inhibitors in the circulating blood, implies their lipid nature. It is assumed that spontaneous conversion of plasminogen to plasmin is taking place all the time, although to a very limited extent ; the reason why there is no clot-lysis under these conditions is perhaps due to the presence of an inhibitor (antiplasmin), acting against plasmin. If this explanation is correct then chloroform–methanol mixture actually removes this inhibitor from the blood ; the fibrinolytic enzyme thus set free acts on fibrin clot (Fig. 1). The fact that serum-treated streptokinase exhibits much higher clot-dissolving activity than the chloroform–methanol-treated serum (Table 3), and also the fact that streptokinase cannot enhance fibrinolytic activity in bovine serum suggest that it must be acting in an entirely different way. The question is what it does then ?

Streptokinase, as is known, combines with a pro-activator present in blood to form an activator which then converts plasminogen to plasmin. The activator has all the properties of a proteolytic enzyme[10] ; and it is known that the conversion of plasminogen to plasmin can also be induced by trypsin or other mould enzymes[11]. Streptokinase has no proteolytic or esterase activity of its own ; most probably it removes some specific inhibitor (anti-activator) from the circulating blood thereby facilitating the conversion of plasminogen to plasmin by the activator thus set free. In this scheme the consideration of the hypothetical pro-activator is superfluous. The reason why bovine serum, after treatment with streptokinase, does not acquire any fibrinolytic activity might be due to the absence of the activator in such serum.

(in the presence of the activator)
Antiplasmin (lipid or lipoproteins in nature) acts as inhibitor
Clot lysis

Fig. 1. Mechanism of action of streptokinase and chloroform/methanol mixture in the generation of fibrinolytic activity in blood.
Streptokinase removes the factor which inhibits the activator, whereas chloroform/methanol mixture removes the antiplasmin. Removal of low-density lipoproteins from serum is the removal of the antiplasmin

Table 3. Fibrinolytic Activity of Sera after Activation with Streptokinase

Normal group			Atherosclerotic group		
No.	Age	,Time for clot lysis	No	Age	Time for clot lysis
1	32	4m. 20s.	1	65	4m. 35s.
2	39	4 40	2	58	4 40
3	33	3 55	3	62	4 48
4	36	3 50	4	72	4 40
5	31	4 10	5	64	4 30
6	32	4 05	6	67	4 35

To each 0·25 ml. serum, 0 025 ml. streptokinase solution was added; this mixture was allowed to stand for 30 min. at 37° C. To this mixture 0 25 ml. purified fibrinogen solution was added and 0·025 ml. thrombin (10 units/ml.) was added to produce the clot. The time required for complete lysis at 37° C. was noted in each case.

Heavy fatty meals, particularly when eaten by atherosclerotic patients, will have, as would be expected, an immediate effect on fibrinolysis. An increase in the phospholipid content of the blood under these conditions has been reported[12] and their importance in clotting has been also demonstrated[9]. Under these conditions one might even expect a reduction in clotting time.

It thus appears that the primary cause of death among atherosclerotic patients after a heavy, fatty evening meal is the failure on the part of the circulating blood to cause lysis of small clots formed in small arteries. However, the positive effect of phospholipids on blood clotting must not be overlooked, since this effect is at least partly responsible for enhancing clot formation. The relative frequency of attacks among aged people of coronary thrombosis in the evening or after retiring may possibly be related to the above observations.

This work has been carried out in the Department of Mycology at the Institute of Laboratories, Forest Hill, Mass. I thank Mr. James B. Gray for providing me with facilities to carry out the work. I also thank Johnson and Johnson Research Foundation for financial support.

BIOPHYSICS

Effects of Ultrasonic Radiation in *Escherichia coli B* using Fluorochrome Acridine Orange as a Vital Stain

Strugger[1], one of the pioneers who introduced acridine orange as a biological fluorochrome, observed that dead cells take up more of this dye, and under ultra-violet excitation fluoresce red, whereas living cells take up less dye and fluoresce green. This difference in the fluorescence is often used as a test for viability of cells and is referred to as 'Strugger effect'[2]. Loss of viability associated with red fluorescence has also been confirmed by Krebs and Gierlach[3] in their work involving radiobiological action on *Allium cepa* cells. Later work has shown that green acridine orange fluorescence in normal cells is to be associated with cell constituents rich in deoxyribonucleic acid[4]. It is also known from the observations of Beers *et al.*[5], Bradley and Wolf[6], and Ranadive and Korgaonkar[7], that deoxyribonucleic acid can form two complexes with acridine orange. One of these complexes is formed when the relative concentration of acridine orange to deoxyribonucleic acid is low, and exhibits strong green fluorescence and the other occurs when this ratio is high and shows orange or red fluorescence. Shift of fluorescence from green to orange is a critical step in this transition, whereas further change from orange to deep red is not sharp and occurs with further increase in concentration of acridine orange, without involving formation of new complexes. 'Strugger effect' may be explained in terms of these observations as a kind of damage to structures rich in deoxyribonucleic acid in the inactivated cells. This results in their high uptake of acridine orange to such an extent that the corresponding fluorescence is copper red. Few observations, however, are available to indicate the nature and extent of damage near the critical point when the shift of fluorescence from green to orange just occurs. A study of this nature in relation to viability was carried out by us on *E. coli* using ultrasonic waves for irradiation and the findings are reported here.

The ultrasonic generator used in this work consisted of a radio-frequency oscillator and a high-voltage power supply unit built in this laboratory by one of us (V. G. T.). The output of the oscillator was link-coupled to a barium titanate transducer having a resonant frequency 1·6 Mc./sec. The transducer was in the form of a tube 2 in. long and 1 in. inside diameter, into which the glass tubes containing bacterial suspensions were introduced. The transducer was kept immersed in transformer oil which acted as a coupling medium for ultrasonic energy from the transducer to the experimental material. The transducer was worked at its resonant frequency, which was continuously checked during the observations with a loosely coupled wave meter (General Radio type 556*A*). The power of the ultrasonic generator was controlled by using a 'Variac' in the primary circuit, and the monitoring was carried out continuously during irradiation with the help of a 2 5-amp. resonant frequency meter in series with the transducer and a vacuum tube voltmeter across it. A Rhode and Schwartz electronic multimeter type *URI BN* 1050 was used for the purpose. During all the exposures the current passing through the transducer was kept constant at 1 amp. and the voltage across it 10 9 V. under loaded conditions. The resonant frequency power fed to the transducer under these conditions worked out to be $\approx$ 0·25 watt/cm.^{2}. Even for the highest exposure employed the overall heating of the suspensions was within 2 deg. C.

Escherichia coli strain *B* obtained from the National Chemical Laboratory of India, Poona, was used. Inocula from fully grown agar slants were allowed to grow in nutrient broth (Difco), for 24 hr. at 37° C.

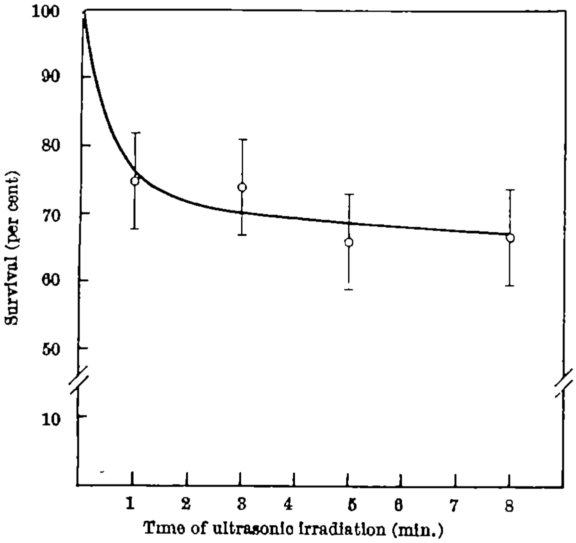

Fig. 1

The organisms were centrifuged, the pellet washed twice and finally suspended in 4·5 ml. buffered saline (pH 7·4). Aliquots of 0·5 ml. from such suspensions were diluted (1 : 10) and exposed to different doses of ultrasonic radiation maintaining suitable controls. The cells were assayed for viability by adopting the standard plating technique. Sterile conditions were maintained throughout the work and observations were repeated several times. The results of a typical set are shown in Fig. 1.

For the examination of fluorescence, measured quantities of control and treated bacterial suspensions were mixed with equal volumes of acridine orange solutions (conc. 0·05 per cent) in veronal buffer (pH 5·3). After an interval of 10 min., smear preparations of the stained material were made on glass slides (Gold-seal). The fluorescence of the vitally stained material was observed under a Reichert 'Lux U.V.' fluorescence microscope. A mercury arc lamp with a blue transmitting filter No. 8027 was used as a light source and blue cut-off filter No. 8006 was placed over the eyepiece.

In the untreated population, green fluorescence was observed, in almost all the cells. Preparations receiving even a few seconds exposure to ultrasonic radiation showed cells with orange fluorescence. Exact cell count was not possible under the limited magnification available with the fluorescence microscope. The occurrence of orange fluorescing cells increased with the dose, and with about 1 min. exposure almost the entire population turned orange. Further treatment did not show any noticeable change in this fluorescence within the dose-range covered in these experiments.

Some of the ultrasonically treated suspensions were inoculated into liquid media, allowed to grow, and observations on fluorescence were made as above on these. Orange fluorescence was noted, and cells with green fluorescence could scarcely be observed. Confirmatory evidence for the persistence of orange fluorescence in the subsequent generations was obtained from the observations on cells picked up from isolated colonies grown on nutrient agar plates, from the treated suspensions.

The salient points from these observations are: (1) Ultrasonic treatment at the intensity-level employed shows about 25 per cent loss in viability in *E. coli* after 1 min. of exposure and no appreciable further loss is noted even with prolonged treatment up to 8 min. (2) Such a treatment also causes a shift of fluorescence from green to orange on staining the cells with acridine orange. (3) An exposure of 1 min. is sufficient to bring about such a change in fluorescence in almost the entire population. There is no indication of a threshold dose even at the lowest dose employed. (4) The altered response to acridine orange staining persists in the subsequent generations observed.

From these findings it appears that if copper red fluorescence is to be associated with total inactivation of the cells as observed by Strugger and other workers, there is a wide gap in the cell damage between such a stage and the point close to the critical shift of green fluorescence to orange. More than 70 per cent of the cells showing orange fluorescence are found to retain their viability. Thus, the capacity for growth of the cell as a whole as well as the replication potential of its genetic material (which is considered to be chiefly involved in the fluorescence shift) is retained to a large extent. The cell at this stage seems to be physiologically closer to the normal cells than to the totally inactivated ones. Besides, there is an indication that it has acquired a degree of resistance to ultrasonic inactivation. The observed persistence of the altered response to acridine orange staining on sub-culturing is also interesting from its genetic implications and needs further investigation.

One of us (S. S. R.) expresses his thanks to the Council of Scientific and Industrial Research (India) for the award of a research fellowship, during the tenure of which this work was carried out.

RADIOBIOLOGY

Retention of Zinc-65 in the Bones of Rats

The distribution and retention of zinc-65 in the organs and tissues of both normal and tumour-bearing animals has been studied extensively[1-4]. Most of these observations, however, have extended only over short periods following administration of zinc-65 and little attention has been paid to the retention of the isotope in bone. Ballou[5] and Gilbert and Taylor[6], in work extending over periods of up to 300 days, have shown that there is a prolonged retention of zinc-65 in bone.

In the present investigation the retention of zinc-65 in the bones of rats has been observed over

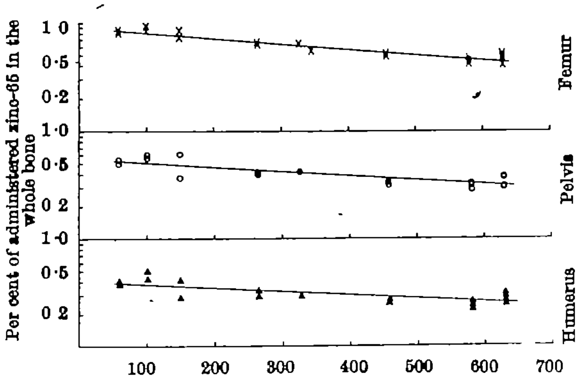

Fig. 1. Retention of zinc-65 in the femur, pelvis and humerus of 'August' rats

a period of 630 days following intravenous injection of the isotope.

The animals used were male rats, seven weeks old, and of the highly inbred, brown-hooded, August strain. Each animal received 2 μc. zinc-65 administered intravenously as a 'zinc-65 serum protein complex'. The preparation of this complex and other experimental details have already been described[6]. The animals were killed in pairs at varying times after injection and the femur, humerus, pelvis and ribs were assayed for zinc-65 and total zinc content.

The retention of zinc-65 in the femur, pelvis and humerus over the period from 58 to 630 days after injection is shown in Fig. 1. In each case it will be seen that, over this period, the retention can be described by a single exponential function. The equation for each bone, together with the appropriate half-times and the standard error of the rate constants, are given in Table 1.

Table 1

Bone	Equation	Half-time (days)	Regression coefficient ± *S.E.*
Femur	$0·91\,e^{-0·00116t}$	598	0·00116 ± 0·00012
Pelvis	$0·56\,e^{-0·00092t}$	752	0·00092 ± 0·00015
Humerus	$0·40\,e^{-0·00074t}$	941	0·00074 ± 0·00017
Mean	—	738	0·00094 ± 0·00024

The specific activities of zinc-65 in the various bones are shown in Table 2. It will be seen that, 7 days after injection, the zinc-65 has been distributed approximately uniformly throughout the zinc contained in the skeleton. The total zinc content of all the bones which were examined continued to rise throughout the period of observation; the values shown in Table 3 indicate that the zinc content of the femur, pelvis and humerus, expressed as μgm. zinc/gm. of bone, do not differ significantly from each other at any age. The zinc content of the ribs does not increase as much as that of the other bones.

Table 3. VARIATION OF ZINC CONTENT OF BONES WITH AGE

Age (days)	Femur	Humerus	Pelvis	Ribs	Mean (excluding ribs)
56	77 ± 7	83 ± 5	70 ± 6	85 ± 6	77 ± 3
103	104 ± 2	99 ± 5	101 ± 6	83 ± 4	102 ± 2
149	102 ± 5	116 ± 6	103 ± 18	71 ± 0	107 ± 6
198	105 ± 8	117 ± 13	102 ± 2	112 ± 7	110 ± 5
313	133 ± 8	130 ± 15	146 ± 3	105 ± 8	136 ± 5
679	191 ± 5	198 ± 11	211 ± 8	149 ± 12	200 ± 4

Zinc content of bone, μgm. zinc/gm. wet bone ± standard error All values are means of results from 2 animals except values for 679 days. These represent the mean for 4 animals.

The half-times for the retention of zinc-65 in the three bones are probably not significantly different from each other, although it appears that retention in the humerus is more prolonged than in the other two bones. The half-time reported here for retention in the femur is somewhat greater than the value which may be inferred from the results reported by Ballou for the retention of zinc-65 in the femur of Sprague–Dawley rats.

The mean half-time for the retention of zinc-65 reported here is much shorter than the corresponding half-time of 1,610 days for the retention of calcium-45 in the bones of rats of the same age and strain (Taylor, D. M., unpublished observations).

Assessment of Dietary Strontium-90 through Urine Assay

SINCE the manner in which the body handles ingested strontium is quite well established[1–3], the chief problem of determining the relative strontium-90 hazard from food concentration data is that of defining the overall average diet with precision. Thus the usual problems concomitant with obtaining dietary intake for nutritional or other purposes apply. In addition to this there is the rather severe problem, generally of minor importance with respect to nutrients, of selecting for assay representative aliquots

Table 2. SPECIFIC ACTIVITY IN PERCENTAGE OF INJECTED ACTIVITY/MGM. ZINC

Time (days)	7		58		100		149		264		630			
Animal No.	1	2	3	4	5	6	7	8	9	10	18	19	20	21

of individual food items. Whereas differences in the vitamins or mineral content by a factor of two are rare for a given food, differences in strontium-90 content by a factor of ten or more are not uncommon[4].

The variations due to latitude[5] and rainfall[6] have long been recognized. In addition, the pattern of rainfall during the growing season is also critical, particularly with respect to cereals[7]. Thus wheat grown on fields only a few miles apart may differ markedly if one got a local shower two weeks before harvest and the other did not.

In view of these problems, it was proposed to use urinary concentration as an independent index of strontium-90 ingestion. By virtue of interchange with soft tissues and other labile strontium-90 depots, such a sample would represent some averaging of the ingestions over a period of days, although the most recent meal would play the most dominant part. Such a sample would also circumvent the problem of getting diet information which may be biased due to the presence of the observer. One can bring additional food to a few meals or think of extra items for an interrogator with much more facility than he can change his excretion-rate.

A study of dietary strontium-90 in particular military groups, together with its concentration in corresponding urine, has been conducted in three countries in co-operation with the Interdepartmental Committee on Nutrition for National Defense of the National Institutes of Health and Department of Defense. The Committee regularly conducts dietary surveys in connexion with nutrition studies in various countries around the world. Representative composite diets are obtained for nutrient assay and aliquots of these have also been used to determine dietary strontium-90. In a number of the local investigations of military units large samples (approximately 12–15 litres) of urine were also obtained, these being random collections representing a large number of men in each case.

Comparative data on diet and corresponding urine for various locations in Peru, Ecuador and Vietnam are given in Table 1. It is noted that the food/urine concentration ratio in terms of μμc. strontium-90/gm. calcium is approximately 2 on the average in each of the three countries investigated. The relation is about the same on the rice diet of Vietnam, which is relatively high in strontium-90 as in Peru and Ecuador. It is concluded from these results that for monitoring purposes strontium-90 concentration in urine gives a reasonable index of the dietary level.

Table 1. COMPARISON OF STRONTIUM-90 CONCENTRATION IN FOOD AND URINE. μμc. STRONTIUM-90/GM. CALCIUM

	Food	Urine	Ratio
Peru			
Arequipa	2·72	1·31	2·1

Duc My	13·8	3·9	3·5
Danang	17·0	8·5	2·0
			Ave. 2·1 ±0·7

The question of which of the two indices is the more reliable under these conditions of field operations cannot be answered on the basis of the present findings ; but there is an indication that the urine values may be the better of the two. Whereas the mean deviation of the individual ratios from the average is 12 and 18 per cent in Peru and Ecuador, it is 33 per cent in the case of Vietnam. This may reflect two special difficulties encountered with the Vietnam diet. In Vietnam the diet is composed of more than 80 per cent rice and, as noted, grains in particular fluctuate markedly in their strontium-90 content. Thus an individual food composite taken on a given day would be less representative of the overall picture than the same sample taken in Western culture or South America. Secondly, small fish, shrimp, etc., which commonly make up a portion of the Vietnam diet, are typically incorporated into the 'stew' and may be eaten, bones and all. Strontium-90/calcium ratio in fish is generally very low compared with other foods, and thus this fluctuating parameter would also reduce the validity of short-term composite diet data with respect to the strontium-90 component.

It is concluded that : (1) composite food and urine data on the population groups reveal that the food/urine concentration ratio of strontium-90 in terms of μμc. strontium/gm. calcium is about two ; (2) for monitoring purposes, the urine strontium-90 concentration is a satisfactory index of ingestion. Urine data may be the more reliable under some conditions of field observation.

This work was supported by the U.S. Atomic Energy Commission under contract *AT* (30–1)–1656. The food and urine samples were collected by survey teams of the Interdepartmental Committee on Nutrition for National Defense. Team members of particular note in this phase of the survey included Jerome Uram and Ogden Johnson (Peru), Gerald Combs and Alvin Wolfe (Ecuador) and C. Frank Consolazio and Albert N. Booth (Vietnam).

The strontium-90 analyses were conducted by Rieta Slakter Hirshman and Karin Bartelsen of the Lamont staff.

HISTOCHEMISTRY

Detection by Fluorescence of Oxytetracycline bound to Bone

Milch, Rall and Tobie[1,2] observed the property of antibiotics of the tetracycline series of becoming localized specifically in bony tissue formed during the administration of these drugs, and persisting in the zone of localization until the structural remodelling has caused the absorption of the bony areas which have bound the tetracyclines. This observation seemed likely to offer a practical and useful method of vital staining, especially for the detection of the turnover of bone.

In fact, the tetracyclines, which are fluorescent in ultra-violet light[3], preserve this property even when bound to bony tissue, and therefore it is possible to detect them by fluorescence microscopy[1,2]. Obviously, if the time pattern of the administration of the drugs is known, it is possible to determine directly the age of the fluorescent bony structures and indirectly the value of the bone-forming activity and its topographical distribution.

As the tetracycline bound to bone is dissolved with bone salts, histological methods which imply decalcification must be avoided. Consequently, the observations of Milch *et al.* were carried out on undecalcified sections prepared by a freezing rotatory microtome; the limited size of sections obtained by this method inevitably is a disadvantage.

I found that fixation in formaldehyde, in alcohol, or in acetone modifies, but does not destroy, the fluorescence of oxytetracycline bound to bone. Thus I was able to use the method of Sognnaes *et al.*[4], embedding the specimens in methyl methacrylate and preparing sections ground with emery paper. In this way the sections obtained are thin enough for the perfect detectability of fluorescence in the microscope.

All this is strictly necessary when the specimens to be examined consist not only of bone but also of soft tissues. The details of this method, which permits the study of sections of unlimited size, together with the technique used in fluorescence microscopy, have been described elsewhere[5].

The results obtained with experimental material and from biopsy and necropsy specimens reveal that the method of vital staining of bone with tetracyclines has a significant advantage over the common method of labelling bone with isotopes. In fact, the optical resolution in fluorescence microscopy is much higher than that allowed by the granular form of autoradiographic emulsions.

In sections prepared by embedding in methyl methacrylate and grinding, the fluorescence is distributed in different patterns according to the structure of the bony tissue. In actively growing bones mainly of a parallel-fibred, finely bundled structure, one can observe yellow fluorescent areas alternating with other areas without yellow fluorescence.

In adult animal and human bone, which mainly consists of lamellar bone, one can observe at times large and homogeneously yellow fluorescent rings or bands, composed of various 'lamellæ', and at other times, thin yellow fluorescent rings or lines, arranged singly or serially, composed of only one 'lamella'.

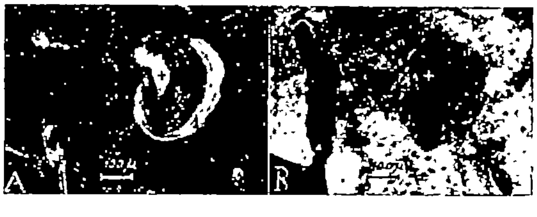

Fig. 1. Undecalcified section, 50μ thick, from the radius of a three-year-old dog, which received three successive administrations of oxytetracycline. (*A*) shows the fluorescence in white; (*B*) is the microradiograph of the same field. The first administration of oxytetracycline is represented in (*A*) by three fluorescent parallel rings (1), the second by two fluorescent rings (2), the third by the fluorescence of the central osteoid edge of the Haversian system (+)

As a rule, different values of mineralization correspond microradiographically to the differences in age as revealed by the fluorescent areas (see Fig. 1).

In adult human lamellar bone, the persistence of tetracycline fluorescence localized in bony tissue has been observed more than seven months after administration, with some variations in intensity and colour of the emitted fluorescent light. This persistence is determined by the quickness of the remodelling process and, perhaps, by differences in mineralization patterns of bony tissue.

These results will be discussed more fully elsewhere.

This method, with its specificity and its advantages as compared with the radioisotope-labelling method, can be appropriately applied to the study of any physiological and pathological bone problems which require a precise knowledge of the age of the structures. It would indeed be very useful to have a complete understanding of the chemical nature of the binding of tetracyclines to bone, as this would allow a better explanation of the mineralization of the bone.

Histochemistry of Human Sublingual Glands

BIOLOGICAL work on salivary glands has revealed that sialic acid is the only acidic component in the bovine submaxillary gland and probably in the sublingual gland of the rat[1-3]. These findings resulted in the elaboration of a method for the removal of sialic acid in tissue sections known to contain abundant amounts of this sialo-mucin[4,5]. Such a method consisted of exposing the sections to acid hydrolysis at different *p*H's and temperatures.

It was then decided to evaluate human sublingual glands histochemically using alcian blue, safranin *O*, and azure *A* for acidic polysaccharides and periodic acid–Schiff for glycoproteins. The glandular mucous acini always showed metachromasia with azure *A* and safranin *O* and a great affinity for alcian blue and periodic acid–Schiff.

Sections of tissue were then incubated in Walpole buffer solutions at *p*H 2·5 at 55° C. and 80° C. for 2–16 hr. It was found that only incubations at 80° C. for 16 hr. resulted in a slight loss of alcian blue and azure *A* staining, and considerable diminution in safranin *O*-positive material.

In an attempt to classify the nature of the substance or substances that presumably were not affected by mild acid hydrolysis, sections were exposed to the action of testicular hyaluronidase for varying periods of time of 1–3 hr. This procedure did not reverse metachromasia or the affinity for alcian blue, thus indicating that the acinar material contained sulphated polysaccharides other than chondroitin sulphate *A* and/or *C*, which are readily hydrolysed by hyaluronidase. In order to determine whether chondroitin sulphate *B* or a closely related substance was present in the acini, tissue sections were then incubated in 1 *N* hydrochloric acid at 80° C. for 10, 30 and 60 min. This treatment caused only a partial decrease in staining.

Because chondroitin sulphate *B* may be removed by acid hydrolysis, these findings would seem to suggest that human sublingual glands contain a heparin-like substance alone or in addition to a sialo-mucin.

Incubations of tissue sections in papain and pepsin for periods of time up to 1 hr. did not affect the periodic acid–Schiff, alcian blue and metachromasia, while prolonged incubations (3 hr.) diminished the staining reactivity of the acini. These findings are opposite to those observed in bovine submaxillary and rat sublingual glands, in which even short incubations with either proteolytic enzyme completely removed all the staining materials. The observations relative to human sublingual glands would indicate that significant species differences exist in the composition of salivary mucins. These results are also of interest in the light of the results reported by Pusztai and Morgan[6] on their work on the effects of papain and ficin on blood-group-specific mucopolysaccharides. These authors demonstrated that dialysis following exposure to proteolytic enzymes failed to reveal demonstrable amounts of sugars and oligosaccharides.

These findings, together with the observation by Tasiro[7] that human sublingual gland is one of the richest sources of blood-group substances, suggest the possibility that some of the polysaccharides in human sublingual mucin are closely related to blood-group substances.

PATHOLOGY

Induction of Melanotic Tumours in the White ('Partial Albino') Syrian Hamster

DELLA PORTA *et al.*[1] first reported the induction of melanotic tumours in the skin of Syrian golden (agouti) hamsters after topical applications of 7,12-dimethylbenz(*a*)anthracene (DMBA). This finding was afterwards confirmed by these and other investigators[2–5]. Ghadially and Barker[5] have postulated that the melanotic lesions arise from dermally situated perifollicular networks of melanocytes intimately associated with certain hair follicles. They suggest that the proximity of dermal melanocytes to sebaceous glands of hair follicles renders them especially vulnerable to the action of carcinogens topically applied to the skin. Recently, Illman and Ghadially[6] have reported the induction of melanotic tumours in the general body skin of white ('partial albino') Syrian hamsters during repeated topical applications (22 weekly treatments) of 2 per cent DMBA in acetone. It is noteworthy that white hamsters characteristically possess a white hair coat, and grossly detectable pigmentation is restricted to the skin of the ears, perineum and genitals; a darkening of eye colour may occur with advancing age[7,8]. Whiteness of hair coat is a genetically determined trait inherited as a simple Mendelian recessive[7,8]. The purpose of this communication is to report observations made in our laboratory on the occurrence of melanotic lesions in white hamsters treated with DMBA.

In our experiments, initiated without knowledge of those of Illman and Ghadially[6], 10 male and 10 female random-bred white hamsters, 4 months old at the start, were treated once weekly for 3 consecutive weeks with a 1 per cent solution of DMBA (Eastman) in mineral oil, essentially the same procedure as that of Shubik *et al.*[3]. Before the first treatment, the hair was shaved from the backs of all animals by means of electric clippers. Each treatment consisted of the delivery by pipette of 4 evenly spaced drops of the carcinogenic solution to this region. It was estimated that each drop of solution represented a delivered volume of 20–30 µl.; that is, it contained 200–300 µgm. DMBA.

Raised nodules were observed in the treated areas 15 weeks from the start[3]. Undoubtedly, they were present prior to this time, for some lesions were already 3–5 mm. in greatest diameter. The vast majority did not exceed a diameter of 2 mm. and in many cases appeared flat to gross inspection. By the eighteenth week, more nodules were evident, and many of the older ones had increased in size. The nodules ranged in colour from pink-white through brown to an intense black. Certain lesions recorded as pink on first observation were noted as grey-black 3 weeks later. Both light and dark nodules were present in the same animal, and there was no clear correlation between nodule size and gross pigmentation. Of 20 hamsters, 19 survived to the fifteenth week after treatment. Of these, 18 had at least one nodule at that time. The remaining hamster, a male, showed evidence of raised nodules by the eighteenth week after treatment.

Shubik *et al.*[3] have designated pigmented nodules exceeding 2 mm. as melanotic tumours. At the time of writing (20 weeks), 8 surviving females have a total of 34 spots 2 mm. or more in greatest diameter on the dorsum, including the tail; the corresponding value for 8 surviving males is 44. Although occasional lesions now exceed 6 mm. in diameter, most lesions are as yet smaller than 2 mm. The total population of dorsal spots on surviving hamsters is now 99 for the females and 112 for the males. In addition, 11 pigmented lesions have been noted in or near the margins of the eyelids. These lesions vary from deep red to black in colour, and one is now approximately 7 mm. in diameter. Such lesions have not been reported previously for the white or pigmented hamster. It is possible that the spread of the carcinogen through wiping would account for the occurrence of pigmented lesions outside the areas directly treated with DMBA. No association of the costo-vertebral spots with pigmented lesions has as yet been noted.

Microscopically, the dorsal lesions appear quite similar to those described by Illman and Ghadially[6] for the white hamster, and by Della Porta *et al.*[1] and Ghadially and Barker[5] for the golden (agouti) hamster. A variable content of melanin granules would appear to be directly correlated with gross observations of the colour of the lesions. As previously reported[4], the pigment granules react positively with silver staining (Fontana) and are bleached by potassium permanganate. The lesions are highly vascularized, and are composed of cells mainly polyhedral or spindle-shaped. They are clearly dermal in location, although they intimately invest hair follicles[5,6]. The association of the melanotic tumours with hair follicles is especially evident in serial sections of skin where care is taken to obtain longitudinal sections of hair follicles. In some instances, the impression is gained that the lesions merge with follicular structures. The proximity of melanotic lesions to hair follicles provides further evidence that the pilosebaceous apparatus is an important channel for the entry of topically applied carcinogens into skin[8,9].

Nevertheless, the origin of melanotic lesions in the white hamster is as yet uncertain, for perifollicular networks of melanocytes have not been identified in this variety by Illman and Ghadially[6] or by us. It has been suggested[6] that melanotic tumours in white hamsters are derived from a system of amelanotic perifollicular melanocytes. Indirect evidence supporting this view is our preliminary observation that repeated topical applications of croton oil result in an increased number of perifollicular melanocyte nests in the golden hamster. Thus it would appear that dermal melanocytes may be present in an amelanotic state, at least in this variety of hamster. The possibility that melanotic lesions are derived from hair follicles cannot as yet be entirely excluded. This explanation has been given by Szabó[10] for the origin of melanotic spots in pigmented mice treated with DMBA and croton oil. It is hoped that the present experiments dealing with the effect of repeated topical applications of croton oil on white hamsters will shed some light on this problem.

Toxicity and Anti-leukæmic Effectiveness, in Mice, of 4-Amino-4-deoxy-N^{10}-methyl-5,6,7,8-tetrahydropteroylglutamic Acid (Tetrahydroamethopterin)

IT has recently been reported[1] that the 5,6,7,8-tetrahydro derivatives of the folic acid antagonists aminopterin, N^{10}-formylaminopterin and amethopterin have a greater inhibitory action on the growth of *Streptococcus faecalis R* and *Pediococcus cerevisiae* than the unreduced analogues. It was therefore of interest to determine whether the greater inhibitory action found in the bacterial system is also reflected in a mammalian system, by an increase in host toxicity and/or anti-leukæmic activity.

Amethopterin and its tetrahydro derivative were chosen for a comparative study. The former is used regularly in our Laboratory[2] as a standard drug for the evaluation of new anti-leukæmic agents, and its toxicity to normal mice is well established. Tetrahydroamethopterin was prepared according to the method of Kisliuk[1,3], and for injection was dissolved in a vehicle of 0·6 per cent potassium ascorbate in 2 per cent aqueous sodium bicarbonate. The solution was stored frozen in rubber-sealed vials under hydrogen in the dark. Under these conditions, tetrahydroamethopterin appears to be stable for several days. Amethopterin was also dissolved in the ascorbate–bicarbonate mixture.

Hybrid male *CDBA* mice [(*BALB/cAn* × *DBA/2J*)F_1], 12–13 wk. old and weighing 24–28 gm. at the beginning of the experiment, were used in this work. Normal mice, mice bearing advanced leukæmia *L*1210 (amethopterin-sensitive) and mice bearing advanced leukæmia *L*1210–*M*46*R* (amethopterin-resistant)[4] were divided into groups and given daily subcutaneous injections of the drugs at 0·01 ml./gm. body-weight. Vehicle and untreated controls were included in each experiment. Records were kept of the weights of the animals and, in the tumour-bearing animals, of the local tumour size.

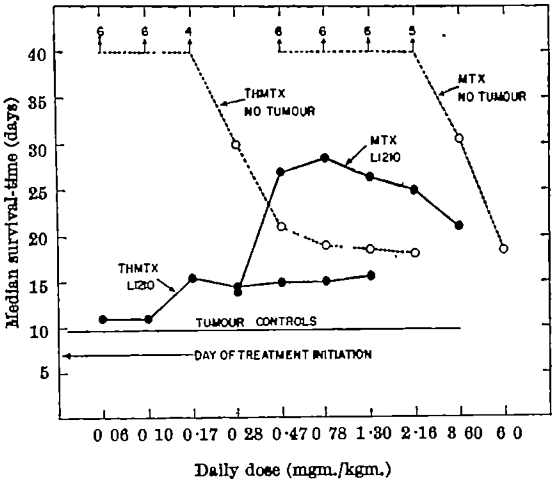

Fig. 1. Toxicity and anti-leukæmic effect of amethopterin (MTX) and tetrahydroamethopterin (THMTX). ○, normal mice, 6 per group; ●, tumour mice, 10 per group. The tumour mice were inoculated subcutaneously in the right inguinal region with about 2×10^6 cells of leukæmia *L*1210 on day 0. Daily treatment was initiated on day 7 after inoculation and continued until the end of the experiment. Treatment of the normal mice was begun on the same day as that of the leukæmic mice. The numerals above the vertical arrows refer to the number of mice in each group which survived until day 40, at which time the experiment was terminated

Table 1. EFFECT OF CITROVORUM FACTOR (CF) ON THE TOXICITY OF AMETHOPTERIN (MTX) AND TETRAHYDROAMETHOPTERIN (THMTX) IN NORMAL MICE

	0·16	6	> 14			

* Six mice per group; each group received daily treatment from day 0 to day 13.

† Mice receiving these dosage-levels had lost considerable body weight by day 14. Other studies of the toxicity of MTX and THMTX in normal mice (Fig. 1) suggests that these animals would have succumbed to continued treatment.

Fig. 1 shows the results obtained for normal mice and mice bearing advanced leukæmia *L*1210. The results obtained with advanced leukæmia *L*1210–*M*46*R* are not included as neither drug caused an increase in survival time over the untreated or vehicle controls, at any of the doses indicated. This would seem to indicate a complete cross-resistance for the tumour to the tetrahydroamethopterin. The toxicity of tetrahydroamethopterin on a daily treatment schedule, in normal mice, was about ten times that of amethopterin. The toxicity of both drugs was manifested by a 25–30 per cent body weight loss prior to death, and the marked melæna observed would indicate severe gastrointestinal mucosa damage (more marked in the case of tetrahydroamethopterin).

With advanced leukæmia *L*1210, amethopterin gave a typical bell-shaped curve when survival time was plotted against logarithm of dose[4]. In contrast, tetrahydroamethopterin gave a flat curve over a similar dose range (0·17–1·30 mgm./kgm./day), and the survival-times in this region were considerably less than for the optimal dose of amethopterin (0·78 mgm./kgm./day). In a second experiment with the tetrahydro derivative a similar flat curve was obtained, and the median survival-time of the mice did not decrease until a dose of 52 mgm./kgm./day was used.

Although both drugs brought about a reduction of the local tumour size during the course of treatment, an effective dose of tetrahydroamethopterin, for example, 0·17 mgm./kgm./day, was attended by considerable loss of weight of the host. This is in contrast to amethopterin, where an effective dose, for example 0·78 mgm./kgm./day, caused no loss of weight over the same time span. Thus, it appears that toxicity to the host is a severely limiting factor in the treatment of advanced leukæmia *L*1210 with tetrahydroamethopterin.

Since previous work has shown[5] that the toxicity of folic acid antagonists, in mice, can be nullified by the concomitant administration of citrovorum factor, but not by injecting folic acid at the same time, it was of interest to determine whether the same relationships existed between tetrahydroamethopterin and these metabolites. To this end, a series of normal *CDBA* mice was given daily doses of amethopterin or tetrahydroamethopterin ranging from non-toxic to toxic levels. A parallel series received 20 mgm./kgm./day of citrovorum factor (calcium leucovorin) with the drug. The results are shown in Table 1. Citrovorum factor gave complete protection from frankly toxic doses of both drugs. However, in a second experiment in which 20 mgm./kgm./day of folic acid was administered concomitantly over the same dose ranges of the drugs, no protection from toxic doses of either drug was observed. The above observations suggest that amethopterin and tetrahydroamethopterin are acting by similar mechanisms in so far as their toxicity to normal mice is concerned.

It is also of interest to note that the diminished antileukæmic effectiveness of tetrahydroamethopterin, relative to amethopterin, is paralleled by a diminished ability of the drug to inhibit purine biosynthesis

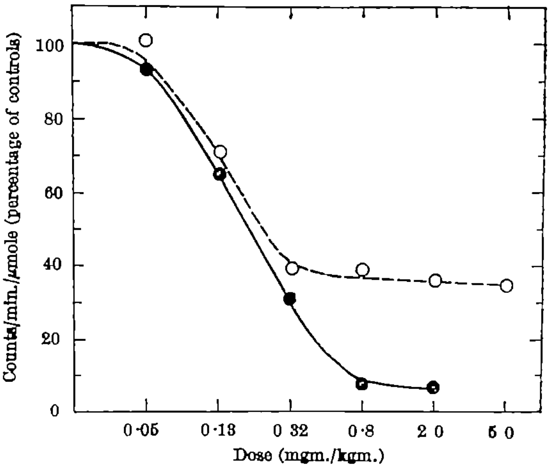

Fig. 2. Effect of amethopterin (●) and tetrahydroamethopterin (○) upon the incorporation *in vivo* of carbon-14 labelled formate into the acid-soluble adenine of mouse spleen infiltrated with leukæmia *L*1210. The experiment was carried out on day 8 after leukæmic inoculation. The mice were given a subcutaneous injection of the drug, then 20 min. later an intraperitoneal injection of 200 μc./kgm. of carbon-14 labelled sodium formate, and were killed after another 20 min. Acid-soluble adenine was isolated from the pooled spleens of three mice, and its specific activity determined (ref. 6). Untreated controls received 2 per cent sodium bicarbonate solution. Results are expressed as

$$100 \times \frac{\text{counts/min./}\mu\text{mole (treated)}}{\text{counts/min./}\mu\text{mole (controls)}}$$

de novo. Previous investigations in our Laboratory have shown[4] that the inhibition of carbon-14 labelled formate incorporation *in vivo* into the acid-soluble adenine of leukæmia-infiltrated mouse spleen can be related quantitatively to the dose of amethopterin administered to the animals. Fig. 2 shows the dose-response curves obtained with amethopterin and tetrahydroamethopterin in this system. It can be seen that, at low doses, both drugs produced similar partial inhibition. However, beyond a level of about 0·32 mgm./kgm. of tetrahydroamethopterin, no increased inhibition was observed. This is in contrast to the marked inhibition produced by higher doses of amethopterin.

The present work has shown that tetrahydroamethopterin is more toxic to normal mice than is amethopterin at equivalent dose-levels. In mice bearing advanced leukæmia *L*1210, tetrahydroamethopterin also appeared to cause somewhat more extensive regression of the local tumour than amethopterin. However, the increased toxicity of tetrahydroamethopterin was proportionately greater than the anti-tumour effect, so that there was a net loss of anti-leukæmic effectiveness. Thus, the toxicity of tetrahydroamethopterin relative to amethopterin for host and tumour cells is, in fact, similar to that reported in the bacterial studies[1]. The biochemical basis for this greater toxicity of tetrahydroamethopterin is not known. One possibility is that it is a more effective antagonist of the reduced, coenzymically active forms of folic acid than amethopterin.

We are doing work on the biological and biochemical activity of the reduced folic acid antagonists.

Ovine Fœtal Resorption caused by *Toxoplasma gondii* Infection

Wastage in ovine reproduction due to infection of the pregnant ewe by *Toxoplasma* has been described in New Zealand[1,2], Australia[3,4] and the United Kingdom[5]. Experimental infection has on several occasions[1,6] confirmed its role as a cause of perinatal mortality. Following experimental infection, ovine toxoplasmosis has now been observed to cause resorption of the fœtus in addition to perinatal mortality.

Experimental infection of ewes, which were 101–122 days pregnant, was effected by intraperitoneal inoculation with undiluted peritoneal exudate from infected mice. Nine ewes were thus infected and kept under surveillance in a small enclosed pen until parturition. Following inoculation, three ewes showed evidence of a sanguineous discharge at the vulva and were therefore killed.

In one ewe, autopsied sixteen days after inoculation, twin fœtuses, which were partially resorbed, were still distinguishable and the placentomes remained intact, although the intercotyledonary component of the fœtal membranes had disappeared. The placentomes showed lesions of focal necrosis similar to those typically seen in cotyledons from infected fœtal membranes[4].

The two other ewes were not autopsied until 30 and 40 days after inoculation, at which stage no fœtus or fœtal membranes remained obvious, however, there was considerable enlargement of the caruncles, these being concave and approximately 1 in. in diameter; a quantity of sanguineopurulent material was also present within the uterus. In view of the fact that the ewes had been under constant observation since inoculation, these findings were taken as presumptive evidence of resorption.

There is no published information concerning total prenatal mortality-rates in flocks in which toxoplasmosis is known to occur naturally; however, results from a Dorset Horn flock in south-eastern Queensland in which perinatal mortality due to toxoplasmosis has been diagnosed, indicate a large discrepancy between the number of ewes apparently conceiving and those eventually lambing. This discrepancy is only partly accounted for by abortions. It is suggested, therefore, that in some circumstances, fœtal resorption may be more important than perinatal mortality as a manifestation of ovine toxoplasmosis.

BIOLOGY

Genetic Control of Oxytetracycline Biosynthesis

More than ten years ago Bonner[1] made an unsuccessful attempt to use inactive variants and biochemical mutants of *Penicillium chrysogenum* for studying the mechanism of penicillin biosynthesis. Since that time the mechanism of the biosynthesis of the antibiotic has apparently not been investigated in this way.

In 1956 we published a paper[2] on the biosynthesis of oxytetracycline by methionine- and niacine-requiring mutants of *Act. rimosus*.

It was shown that both mutants require for the antibiotic production much greater amounts of these substances than is needed for their growth. Repeatedly isolated mutants with methionine and niacin deficiencies had the same properties. These results convinced us of the necessity of investigating the genetical control of the mechanism of the antibiotic biosynthesis, particularly the biosynthesis of oxytetracycline. In this connexion an attempt was made to obtain balanced inactive mutants of the oxytetracycline-producing organism.

At first, under the action of mutagenic factors, namely, ultra-violet light, X-rays or ethyleneimine, inactive variants were obtained, which practically lost the ability to produce the antibiotic ('zero' variants).

Two groups were observed among a great number of zero variants. One group took the form of colonies with very light to almost cream substrate mycelium and white aerial mycelium ('white' group). The other group formed colonies with dark brown substrate and greyish aerial mycelium, which excreted dark brown to almost black pigment into the culture fluid ('black' group).

When two mutants of the 'white' group were grown together on a liquid complex or synthetic medium, they produced no oxytetracycline, whereas when one mutant of the 'white' group was grown together with a mutant of the 'black' group, the activity markedly increased (Table 1). The plating of the mixed culture in Petri dishes showed that only the starting strains when grown together participated in fermentation. The second examination of the mutants with respect to their activity in a pure culture gave no positive results.

The nature of the antibiotic substance, synthesized on mixed submerged cultivation of two inactive variants of *Act. rimosus*, was studied by means of paper chromatography according to the method described by Selzer and Wright[3]. The antibiotic studied proved to be oxytetracycline.

The results of the determination of the antibiotic produced with the help of both the biological and the colorimetric methods coincide.

The studies on cross-transfers of the mycelium throws some light on the mechanism of interaction between the inactive mutants during the oxytetracycline synthesis. The mycelium of the 'black' mutant *T*572, separated from the culture fluid and washed with sterile water, was transferred into a 48-hr. culture fluid of the 'white' mutants *T*12 and *T*999, separated from the mycelium by centrifugation and filtered through a bacterial filter. In all cases of transferring the mycelium of a 'black' mutant into the culture fluid of a 'white' mutant the biosynthesis of oxytetracycline was observed, while in cases of transferring the mycelium of a 'white' mutant into the culture fluid of a 'black' mutant the synthesis was not observed. The behaviour of the 'black' mutant mycelium transferred into the culture fluid of the active starting strain of *Act. rimosus* was the same (Table 2).

Table 1

Strain	Corn steep liquor medium		Synthetic medium	
	Activity (γ/ml.)	Mycelium weight (mgm. %)	Activity (γ/ml.)	Mycelium weight (mgm. %)
Active starting strain	3,046	1,041	1,900	930
*T*1 (white)	0·55	1,095	0·50	1,042
*T*2 ,,	0·20	485	0·20	285
*T*11 ,,	0·41	1,160	0·55	852
*T*12 ,,	0·90	1,360	0·54	1,020
*T*16 ,,	0·80	1,012	0·70	940

*T*999 ,,	0·50	1,042	0·48	787
*T*572 (black)	20·0	872	0·87	752
*T*1 + *T*572	1,030	1,075	790	890
*T*2 + *T*572	790	1,038	600	898
*T*11 + *T*572	830	1,002	490	897
*T*12 + *T*572	1,000	1,083	780	874
*T*16 + *T*572	600	990	600	854
*T*956 + *T*572	720	1,088	670	798
*T*999 + *T*572	760	930	600	870
*T*2 + *T*956	5·0	860	—	—
*T*2 + *T*999	4·0	956	—	—
*T*12 + *T*956	1·0	924	—	—
*T*12 + *T*999	3·0	926	—	—
*T*16 + *T*956	4·0	656	—	—
*T*16 + *T*999	4·0	905	—	—

Table 2

Combination of the mycelium and the culture fluid	Mycelium weight mgm. %		Activity (γ/ml.)			
	Initial	After 36 hr.	Initial	After 12 hr.	After 36 hr.	After 60 hr.
Culture fluid of *T*12 + mycelium of *T*572	1,290	1,384	0·1	106	480	520
Culture fluid of *T*999 + mycelium of *T*572	1,379	1,468	0·2	130	390	420
Culture fluid of *T*572 + mycelium of *T*12	1,520	1,504	0·8	1·0	0·9	1·0
Culture fluid of *T*572 + mycelium of *T*999	1,580	1,600	0·2	0·4	1·0	0·9
Culture fluid of the active starting strain + mycelium of *T*12	1,424	1,431	230	220	260	210
Culture fluid of the active starting strain + mycelium of *T*572	1,214	1,260	270	400	580	640

On the basis of this fact it is possible to assume that 'white' mutants produce some unknown substance (x-substance), which provides the antibiotic synthesis by the mycelium of the 'black' mutant *T*572. It is interesting to note that x-substance is present in the culture fluid of the active starting strain of *Act. rimosus*.

The task of further investigations is to elucidate the nature of this substance.

Modifying Factors of Amino-acid Antagonisms in a Mutant of *Neurospora crassa*

IN certain amino-acid-requiring mutants of *Neurospora crassa*, any one of a number of naturally occurring amino-acids can inhibit competitively the utilization of the required amino-acid for growth[1,2]. In the course of determining the inhibition indexes of the inhibitory amino-acids, it was noted that variations in certain experimental conditions would cause significant differences in the observed indexes. The mutant strain *E*-5212 (ref. 3), which responds to either phenylalanine or phenylpyruvate, was used in a study of the various modifying factors. Growth assays were performed in the usual manner using Fries minimal medium[4]. The inhibition index is defined as the ratio of inhibitor to required amino-acid which produces complete inhibition of growth for approximately three days at 27° C.

A mutant strain of *Neurospora crassa* has been described which requires thiamine or thiazole for

Table 1. EFFECT OF pH AND TEMPERATURE ON INHIBITION INDEXES

optimal growth at temperatures below 30° C. but which grows on minimal medium like the wild-type strain at 35–39° C.[5]. This mutant is inhibited by threonine, and the inhibition is most strongly expressed at 35° C. and at pH values below 5·8 (ref. 6). Table 1 shows that changes in pH and temperature had a much different effect on the amino-acid inhibitions described here than on the threonine inhibition previously reported[5,6]. The inhibition index of L-leucine was 15 at 20° C., but at 35° C. complete inhibition of growth could not be achieved with an inhibition index of 200, the highest index tested. The inhibition index of L-valine increased four-fold over the pH range 6·0–5·2. A mixture of purines and pyrimidines also modified the inhibition index of L-valine. When the components of the mixture were tested individually, the modifying effect was exhibited by two of the purines, guanine and xanthine, as shown in Table 2.

Table 2. MODIFICATION OF INHIBITION INDEX OF L-VALINE BY GUANINE AND XANTHINE

* Figures indicate mgm. dry weight. All flasks contained 0·1 µmole L-phenylalanine.

Mathieson and Catcheside[7] have reported that the growth of a histidine-requiring mutant of *Neurospora crassa* is inhibited by certain amino-acids in combination with lysine or arginine. If, however, the inhibitors were added after two days growth, they had no effect. *E*-5212 exhibited a somewhat similar response to post-inoculation additions of the inhibitory amino-acid, as shown in Table 3. All growth flasks were inoculated at zero time and contained 0·5 µmole of the required amino-acid, L-phenylalanine. The inhibitory amino-acid, L-leucine, was added at the indicated times. It can be seen that by only 8 hr. incubation the mutant was less sensitive to the inhibitory amino-acid. The mutant became increasingly resistant to the inhibitor with time, so that by 18 hr. an inhibition index of 400 was insufficient to inhibit growth completely.

The same effect can be demonstrated by measuring oxygen uptake by the usual manometric methods in a Warburg apparatus. The reaction vessels each contained an equal conidial inoculum and 0·5 µmole of L-phenylalanine in Fries minimal medium. Fifty µmoles of L-leucine was tipped in from the side-arm at the times shown in Fig. 1. By 12 hr., the inhibition was of such a nature that the rate of uptake quickly returned to that shown by the cells with no inhibitor present.

Table 3. EFFECT OF ADDING INHIBITORY AMINO-ACID POST-INOCULATION

Inhibition index (L-leucine)	Post-inoculation time (hr.)							
	0	4	8	12	18	25	36	48
0	41*	40	42	41	43	42	41 (9)†	40 (19)†
10	25	34	35	37	34	38	39	43

* Figures indicate mgm. dry weight after 72-hr growth. All flasks contained 0·5 µmole L-phenylalanine.
† Growth (mgm.) at designated time.

The primary result of the single genetic block in *E*-5212 is the requirement of phenylalanine or phenylpyruvate for growth. On further study, however, it has been shown that growth of the mutant on phenylalanine is subject to inhibition by any one of 14 amino-acids[3]. We have demonstrated here that the amino-acid inhibition, and consequently growth of the mutant, is in addition sensitive to a number of environmental variables. It has not yet been determined if the amino-acid inhibitions observed in *E*-5212 are the result of competition for entry into the cell or of competition for an intracellular site. It is suggested, nevertheless, that the site must be of such a nature that its affinity for phenylalanine and the inhibitory amino-acid is subject to the modifying factors discussed here.

This work was supported in part by grants and contracts from the National Science Foundation.

Response of Japanese Quail to Restricted Lighting

Recent publications on light response of the domestic fowl have directed renewed attention to the fact that a hen's reactions to experimental light stimulation depend, in part, on the conditions prevailing before a given light treatment[1–4]. Short-day lighting of immature pullets may lead to increased rate of egg production immediately following maturation, depending both on the length of pretreatment and light intensities used. Similarly, it has been shown that laying hens held in complete darkness will resume high rates of lay afterwards, even under light intensities considered insufficient when given without a preceding dark period[5]. The work in ref. 5 indicated that short but frequent doses of intense light may over-stimulate hens so that subsequent treatment with continuous light results in reduced rates of lay. A similar experiment with Japanese quail (*Coturnix coturnix japonica*) is reported here, in an effort to establish its usefulness as a pilot animal for the fowl.

Approximately 300 *Coturnix* were reared to 5 weeks of age. They belonged to three closed populations, all derived from the same original stock, but each in their first generation of selection for egg number. Genetically these populations may, therefore, be considered alike. The chicks were brooded in a quail battery and were given weak all-night light from a red 7-W. bulb for the first three weeks. They were then placed in chick batteries under natural daylight. At 5 weeks the birds were sexed and the females moved to single cages with 6 in. × 8 in. floor space ; each population was in a separate location. Two of these were windowless chambers equipped with a light-trap at the entrance. The third room, reserved for the control treatment, was located in an open chicken house. Experimental light treatments were first applied at 6 weeks of age when a few hens had already begun to lay eggs.

Group *A*, the control, was given 14 hr. of light every day, at an intensity of more than 1 foot-candle. Group *B* was given no light, except for such light as required when marking egg cards above the cages. This was done by means of a weak pencil flashlight, shielded to avoid direct exposure of the birds to light. Group *C* was given 1 min. of intense light of approximately 2 ft.-c. every hour. These conditions were maintained until the birds were 12 weeks old. At that time the light regimes of groups *B* and *C* were reversed, giving light at the rate of 1 min./hr. to hens preconditioned in darkness and vice versa. No change was made for Group *A*. At 16 weeks the birds were weighed and placed on normal light.

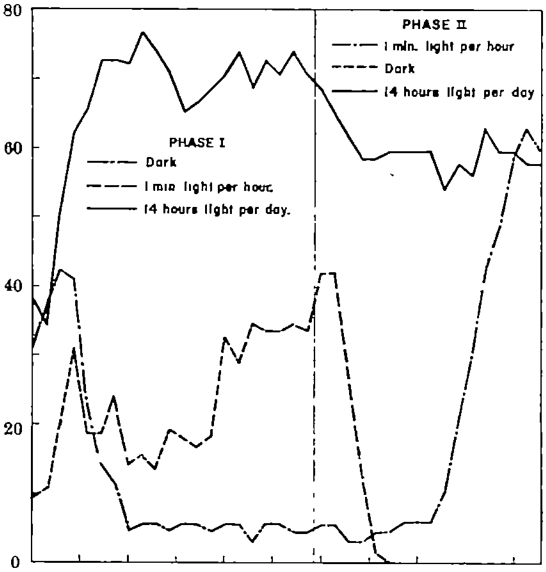

Fig. 1. Dependence of rate of lag on light regime

The response of the hens' rate of egg production to changes in light pattern is shown in Fig. 1. At 6 weeks of age the populations had started to lay at somewhat different rates. The onset of experimental lighting forced most of the hens of Group *B* treated in the dark out of production and prevented those not laying from beginning to do so. Within 2 weeks the rate of production in this group dropped to less than 10 per cent. Similarly, there was some reduction in rate of lay for Group *C* birds under intermittent lighting ; after about 2 weeks this population began a consistent rise in lay up to about 40 per cent by the sixth week of treatment.

After the switch of light regimes the two experimental groups changed their egg-laying pattern radically. Group *B*, previously in darkness, showed a rapid rise in egg production 2 weeks after the change to intermittent lighting. Within 4 weeks these hens had reached or exceeded the rate of lay of control birds. In contrast, the group held in darkness following treatment with intense intermittent light stopped egg production completely within a week of change in conditions, and stayed out of lay beyond 16 weeks of age.

In order to reach a general interpretation of these results, one may consider each type of experimental lighting first in its role as direct stimulus and, secondly, in its function in preconditioning the hens for subsequent lay. One may further consider the period of maturation before 6 weeks of age as preconditioning the hens with 14 hr. of light per day.

Viewed in this manner, the results suggest that intermittent lighting stimulates egg production of hens less than 14 hr. of light per day, but more than complete darkness does. It also seems clear that intermittent lighting following dark treatment is much more effective in its stimulatory role than after pretreatment with 14 hr. of light per day. Conversely it would appear that dark treatment reduced egg production more drastically after hens were preconditioned with intermittent lighting than was the case following the 14 hr. of light a day of the maturation period.

One may conclude that dark treatment of *Coturnix* while almost completely preventing egg production during its application may serve to enhance afterwards the response of hens to light. In contrast, the intermittent light regime permits only sub-optimal productivity unless preceded by a dark period or perhaps other treatment; it has adverse effects on the subsequent ability of hens to lay in darkness, when compared to normal 14 hr. of light per day. These conclusions are in general agreement with results obtained for chickens[1].

Presence of Blood Antigens in Fish Mucus and its Possible Parasitological Significance

WE have recently shown in this laboratory that each species of fish appears to secrete its own specific mucus[1]. The differences between mucus from various species can be detected by chromatographic methods. With closely related species, like *Sebastes marinus* L. and *S. mentella* Travin, several types of chromatographic technique may be required in order to detect any difference between the two forms of mucus[2]. At present we know very little about the nature of this species specificity of the mucus. Some of the chromatographically separable components fluoresce on exposure to ultra-violet radiation and some are ninhydrin-positive.

Fish serum proteins are, of course, species specific, and therefore we have used some specific anti-fish sera to test for the presence of serum protein components in body and gill mucus. The recently described cellulose acetate membrane immunodiffusion method of Consden and Kohn[3], which we have already shown can be used to distinguish between the closely related *Sebastes* species mentioned[2], was used in this work.

Anti-bass (*Labrax morone* L.) serum *R* 923 was produced by injecting bass serum into a 2-kgm. male albino rabbit by a course of subcutaneous injections according to the following procedure: A preliminary injection of 0·5 ml. bass serum was followed after a week by a second similar one with another three days later and a fourth two days later still. The rabbit was bled out under nembutal, a week after the last injection. The antiserum so produced gave a homologous titre of 1 in 12,000 and a photronreflectometer sigma tau value of 152. Oudin[4] and Ouchterlony[5] immuno-diffusion studies showed that it contained at least six distinct antibodies to the homologous serum. Two of these antibodies reacted with components in *Sebastes marinus* serum and one reacted with cod (*Gadus callarias* L.) serum. No heterologous reaction with coalfish (*Gadus virens* L.) serum was detected. Further studies of bass blood are being reported elsewhere[6].

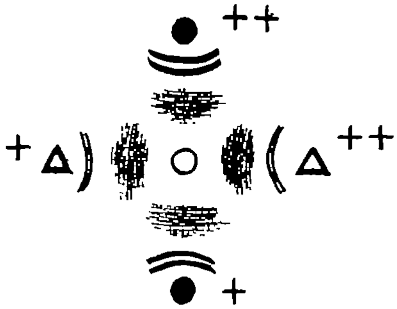

Fig. 1. Diagram of Consden–Kohn reactions between antibass serum *R* 923 (○) and bass mucus (●). Upper and lower reactions are with body mucus and left and right reactions are with gill mucus (△). Plus signs indicate approximate quantities applied. The inner broad bands are nigrosine-positive, the outer lines of precipitation are both ponceau *S*- and nigrosine-positive

When the anti-bass serum *R* 923 was treated with bass mucus using the Consden–Kohn cellulose acetate membrane technique it was found that three antigen antibody (*AnAb*) reactions occurred (Fig. 1). The two outer *AnAb* reactions were detectable by ponceau *S* staining which produced fine clearcut lines of reaction. The more diffuse innermost zone of precipitation was not detectable with ponceau *S*, but required the use of nigrosine staining. It was also found, as can be seen in Fig. 1, that the gill and body mucus reacted somewhat differently. The reactions were stronger with body mucus than with gill mucus. This is perhaps surprising since gill mucus might be more likely to be contaminated with blood than body mucus. It should be pointed out that in the samples studied no contaminating blood was detected. Furthermore, the ponceau *S*-positive *AnAb* reactions were well separated from each other whereas with gill mucus the two lines of precipitate, although discrete, were very close to each other. This would indicate that the relative concentrations of the two antigens involved differ in gill and body mucus.

Anticod serum *R* 712 available from previous work on intragenic relationships in the genus *Gadus*[7] was used to study the body mucus of *Gadus callarias*. Only a single *AnAb* reaction faintly ponceau *S*-positive was found. Subsequent staining with nigrosine gave no further reactions, but the ponceau *S*-positive band stained more strongly.

These results show that some of the serum protein antigens of fishes are also secreted in mucus. These species-specific antigens may be responsible, in part at least, for the ability of certain fish parasites to detect their specific hosts. Wright[8] has pointed out that such parasites must detect their hosts by chemotactic methods, and the presence of species-specific serum proteins in the body mucus suggests a possible basis for this.

Further work is in progress.

Occurrence of a Species of *Halammohydra* on the Isles of Scilly

DURING the period March 24–28, 1959, collections of the interstitial fauna on several shores of the Isles of Scilly were made. On the very sheltered muddy sand shores of the islands of Tresco and St. Martin's, a small number of specimens of the cœlenterate, *Halammohydra* Remane, were recorded, in the surface 5 cm. of sand. The samples were treated with formalin immediately after sampling and this rendered exact identification impossible.

Attempts by one of us (L. A. H.) to collect live specimens at Easter, April 9–23, 1960, were unsuccessful. It may be, therefore, that the earlier presence of the animals was accidental, the true habitat being in the sub-littoral. Alternatively, it may be that these animals exhibit a seasonal cycle and were much less frequent at the time of the 1960 sampling.

The specimens exhibit certain differences from any of the known species, the number of tentacles varying from 9 to 15. Swedmark[1] points out that regional differences occur in the various species.

Slugs at Low Temperatures

DAMAGE by slugs in gardens and farms is usually worst in late autumn and early spring. There are three reasons for this. First, some species are most numerous in winter[1]. Secondly, alternative foods are scarce, and crop plants such as germinating wheat or the young shoots from delphiniums are sometimes almost the only food available. Thirdly, slugs are active at temperatures which would put most cold-blooded animals into chill-coma.

Experiments have shown that different species of slugs have different chill-coma temperatures. *Agrolimax reticulatus*, which is incidentally a most important pest on farms, is particularly well adapted to life at low temperatures. It is not completely immobilized even at 0° C., and at 0·8° C. moves and feeds apparently normally. *Arion hortensis*, an important garden pest, seldom moves spontaneously or feeds below 5° C. *Milax budapestensis* is intermediate in its temperature relations to the other two species, for it is active at 5° C., but is inactive at 0·8° C.

Some years ago I showed that many insects[2], and also amphibians[3], change their chill-coma temperature by several degrees centigrade within 24 hr. when kept at different temperatures. Similar results for fish, though with a longer period of acclimatization, are well known. I fully expected that slugs would behave similarly.

However, *Agrolimax reticulatus* and *Arion hortensis* do not seem to show any low-temperature acclimatization at all. The chill-coma temperature seems to be quite unaffected if these slugs are kept for from 1 to 10 days at (*a*) 5° C. at (*b*) a temperature fluctuating between 0° C. and 10° C., and at (*c*) a constant temperature of 20° C. The explanation for this difference from insects, fish and amphibians has not been found, but slugs seem well adapted to life at low temperatures and do not readily lose this adaptation. The observations of Dainton[4] that dormant slugs become active, in the laboratory, when the temperature falls, is obviously relevant, but the behaviour of these animals under natural conditions in the field needs much further study.

Trapped Primary Product of Photosynthesis in Green Plants

BY use of a suitable method of flash photometry five types of absorption changes (types 0, 1, 2*a*, 2*b*, 3) have been observed during photosynthesis in green plant cells. Measurements under various physical and chemical conditions lead to the following assumptions on the related reactions[1].

The absorption change type 1 is caused by a photochemical reaction on chlorophyll Chl a_1. Probably a metastable state of chlorophyll Chl $a_1^{\bullet}$ ($\tau \approx 5 \times 10^{-5}$ sec.) is formed, which mediates an electron transfer between an electron-donator D and an electron-acceptor A :

$$D(\text{Chl } a_1)A \xrightarrow{h\nu} D(\text{Chl } a_1^{\bullet})A \longrightarrow D^{+}(\text{Chl } a_1)A^{-} \quad (1)$$

The absorption changes type 2 were first observed by Duysens[2] using a static measuring method with excitation of photosynthesis by steady light; equal absorption changes result from the application of flash photometry[1]. These absorption changes are characterized by two negative maxima (~ 420 mμ, 475 mμ) and one positive maximum at 515 mμ. The course of the decrease of absorption as a function of wave-length in the neighbourhood of 420 mμ is comparable with the course of an oxidation of cytochrome[2].

Kinetic experiments carried out by flash photometry led to the conclusion that the absorption changes type 2 ($\tau = 10^{-2}$ sec.) are involved in the primary reactions of photosynthesis[1]. Further we succeeded in splitting up the absorption changes type 2 into two reactions, designated as type 2*a* and type 2*b*, by extraction with cold petroleum ether[3,4]. After extraction the absorption changes at 475 mμ and 515 mμ (type 2*b*) disappear, while a negative absorption change with a shift to ~ 425 mμ still can be seen. Due to the absence of type 2*b*, it is possible to detect a small positive absorption change near ~ 530 mμ which is connected with that at ~ 425 mμ (type 2*a*).

The results of our first measurements of absorption changes at low temperatures were reported at a meeting to discuss fast reactions in solution at Hahnenklee[5] (1959). The reaction type 1 (production of Chl $a^{\bullet}$) occurs at −150° C. in just the same way as at + 20° C. Therefore an electron transfer according to reaction (1) should also be possible at −150° C. The following observations on type 2*a* give evidence of this fact.

On illumination of spinach chromatophores at −150° C. the absorption changes; type 2*b* (475 mμ and 515 mμ) does not occur. The reaction type 2*a*, however, continues to occur at −150° C. On exposure to light, a decrease in absorption occurs at ~ 425 mμ (Fig. 1). Coupled with this decrease at ~ 425 mμ is a small increase at ~ 530 mμ, coincident with the observations made after extraction with petroleum

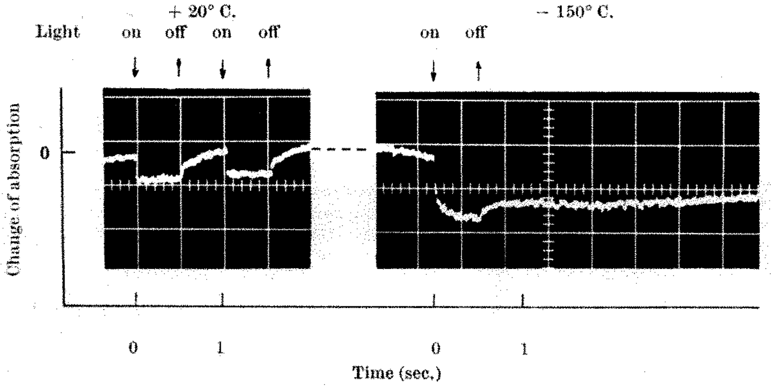

Fig. 1. Changes of absorption at 425 mμ caused by red illumination of chromatophores of spinach

ether. After switching off the light, the absorption changes at ~425 mμ and ~530 mμ, however, are not reversible at – 150° C., that is, a product is trapped at – 150° C. (Only after thawing to 0° C. does a back reaction occur.) These results show that the trapped product is probably one of the two primary products (D^+ or A^-). The course of the negative absorption change as function of wave-length in the range of 425 mμ suggests that the primary product is probably identical with the oxidized form of a cytochrome ($D^+ = \text{cyt}^+$). The small positive change of absorption at ~530 mμ, however, normally does not appear on oxidation of cytochromes. It should be emphasized that the experiments have been carried out with material which was photochemically active after the temperature had been raised from –150° C. to +20° C. (proof by Hill reaction).

An irreversible oxidation of cytochrome at low temperatures in purple bacteria, especially *Chromatium*, has been already reported by Chance and Nishimura[6].

Fixation of Nitrogen-15 by Excised Nodules of *Discaria toumatou*

Discaria toumatou (Rhamnaceae) has previously been recorded as a nodulated plant in New Zealand[1]. The nitrogen-fixing ability of its nodules has now been studied experimentally.

In these experiments seedlings of *D. toumatou* made no growth in aerated nutrient solutions lacking added nitrogen whether nodules were present or not. In solutions containing 5 p.p.m. nitrogen as nitrate only, plants that were nodulated grew normally, non-nodulated plants becoming moribund.

Nodulated plants of *Coriaria arborea*, in contrast, made normal growth in aerated nutrient solutions lacking added nitrogen, but became moribund when nodules were absent. Previous work has shown that excised nodules of this plant are able to fix atmospheric nitrogen[2].

Experiments in which excised nodules of *Discaria* were exposed to an atmosphere enriched with nitrogen-15 have also been carried out. Some nodules for these experiments were obtained from plants dug in the field. The roots were washed free of soil and transferred within 2 hr. to flasks containing an aerated nutrient solution lacking added nitrogen. They remained in this solution for two days before nodules were excised and exposed to nitrogen-15. Other nodules were obtained from plants of *Discaria* growing in aerated nutrient solution containing 5 p.p.m. nitrate nitrogen. Excised nodules of *Coriaria arborea* were exposed to nitrogen-15 at the same time. These were obtained from plants growing in aerated nutrient solutions as shown in Table 1.

All nodules were exposed for 40 hr., as previously described[2], to an atmosphere containing 90 per cent nitrogen enriched with 32 atoms per cent excess nitrogen-15. Nitrogen was then extracted with 3*N* hydrochloric acid.

Table 1. ENRICHMENT OF EXCISED NODULES FROM ATMOSPHERE CONTAINING NITROGEN-15

	Nitrogen-15 enrichment (atoms per cent excess)
Discaria from soil	0·10
Discaria from 5 p.p.m. nitrogen solution	0·095
Coriaria from solution lacking nitrogen	> 0·2
Coriaria from 5 p.p.m. nitrogen solution	0·22
Coriaria from 40 p.p.m. nitrogen solution	0·33

These experiments provide evidence that nodules of *Discaria toumatou* are capable of fixing atmospheric nitrogen. Under the conditions employed, however, they differed from those of *Coriaria arborea* in being unable to supply the plant's total need of nitrogen.

In the field *Discaria* grows quite differently from what it does in solutions: it is spiny and almost leafless. One would suppose that this type of growth uses less nitrogen, and it is therefore possible that the nodules can support the growth of *Discaria* in Nature and, perhaps, even that of its usual associates such as sweet briar (*Rosa rubiginosa*).

BACTERIOLOGY

Lysogenic Conversion in the Genus *Proteus*

THE presence of prophage renders a bacterial cell immune to homologous bacteriophage. Homologous phage often adsorbs and penetrates the immune cell but does not undergo reduction to prophage and its genetic material is gradually 'diluted out' during multiplication of the cell[1]. Burnet and Lush[2] were the first to encounter a variation of this theme. They studied a lysogenic coccus which did not adsorb the homologous phage. Other workers[3,4] have since described systems in *Salmonella* where the presence of prophage modifies adsorption of homologous or heterologous phage. Changes in properties of bacteria occasioned by the presence of prophage are termed lysogenic conversions[5].

The recovery of a series of temperate phages from lysogenic strains of *Proteus* enabled the study of transduction[6] and conversion in this genus. A series of eleven different phages were employed. Phages 12/57, 49/*F*7, 50/*F*7 and 54/*F*7 were obtained by ultra-violet irradiation of *Proteus* strains 12, 49, 50 and 54, respectively. The indicator organism for the phage obtained from *Proteus* 12 was *Proteus* 57, and the indicator organism for phages from *Proteus* 49, 50 and 54 was *Proteus F*7. Phages 34/13 and 36/13 were present in the supernatant fluids of 10-day broth cultures of *Proteus* 34 and 36, respectively. *Proteus* 13 was the indicator organism for both these phages. Phages $\frac{6}{24}/6$, $\frac{12}{57}/57$, $\frac{14}{20}/14$, $\frac{14}{20}/20$ and $\frac{24}{25}/14$ were present in the supernatant fluids of 10-day broth cultures of *Proteus* strains 6 and 24, 12 and 57, 14 and 20, 14 and 20, 24 and 25, respectively. The indicator organisms for these phages were *Proteus* strains 6, 57, 14, 20 and 14, respectively. Organisms 49, 50 and 54 are *vulgaris* varieties of *Proteus*. The remainder are *mirabilis* strains.

Adsorption experiments of homologous phage to the lysogenic *A* phase[7] wild strains were done by adding 1 ml. of phage suspension to 1 ml. of an aerated overnight broth culture of the organism at a multiplicity of infection of 1. After 20 min. at 37° C. the bacteria were rapidly deposited by centrifuging and the clear supernatant titrated for unadsorbed phage. The 20 min. allowed for adsorption is less than the latent period of any of the phages and more than required for 95 per cent adsorption to indicator strains. Control experiments consisted of 1 ml. of the phage suspension in 1 ml. of broth. These were treated like the tests. Results indicate that only strain 54 adsorbs homologous phage (phage 54/*F*7). In this instance the phage titre of the supernatant was reduced from 1×10^9/ml. (control) to 1×10^6/ml. The remaining 10 phages do not adsorb at all to the corresponding wild lysogenic strains.

The lysogenic *Proteus* were irradiated with ultraviolet light according to the method of Lederberg and Lederberg[8]. Among the survivors of strains 12, 34, 36, 49, 50 and 54 colonies were recovered which are lysed by homologous phage. These sensitive variants are presumably organisms which have been cured of prophage as no phage can be recovered from them. Plaques formed by homologous phage on these sensitive variants have turbid centres due to the growth of lysogenized cells. Cultures of the turbid centres yield organisms with identical phage-adsorbing properties to those of the corresponding wild strain. Prophages present in wild strains 12, 34, 36, 49 and 50 are thus converted in respect of phage-adsorbing capacity. Although non-lysogenic derivatives of the hosts of phages $\frac{6}{24}/6$, $\frac{12}{57}/57$, $\frac{14}{20}/20$, $\frac{14}{20}/14$ and $\frac{24}{25}/14$ have not been obtained it is probable that these prophages exert a similar converting effect. Prophage 54/*F*7 is the exception. Lysogenic immune wild *Proteus* 54 adsorbs phage 54/*F*7 as readily as the sensitive variant.

Phages 12/57 and 34/13 previously used in transduction experiments[6] readily lysogenize most cells of the indicator strains (*Proteus* 57 and 13 respectively) at multiplicities of infection > 5. *Proteus* 57 and 13 lysogenized in this manner and labelled 57(12/57) and 13(34/13) respectively were freed of unadsorbed phage by suspending in the corresponding phage antiserum for 30 min. After centrifuging, the serum was decanted and the deposit streaked on MacConkey agar to yield single colonies. These colonies have the following properties:

(1) Broth cultures of 57(12/57) and 13(34/13) spontaneously liberate phage active on corresponding non-lysogenic strains. These phages are neutralized by antiserum to phages 12/57 and 34/13 respectively.

(2) The strains do not adsorb homologous phage.

(3) They are morphologically identical to strains 57 and 13.

(4) *Proteus* 13(34/13) does not adsorb phages 5 and 25. These phages were isolated from sewage and are active on *Proteus* strains 5 and 25 respectively[9]. *Proteus* 13 is lysed by these phages.

(5) Organisms 57(12/57) and 13(34/13) when matched against 57 and 13 respectively in the *A* phases[7] on nutrient agar show positive Dienes[10] phenomena, that is, they do not swarm into each other and maintain a clear line of demarcation. Fig. 1 illustrates this reaction between strains 57(12/57) and 57. The antigenic differences involved which are responsible for this phenomenon have not yet been identified.

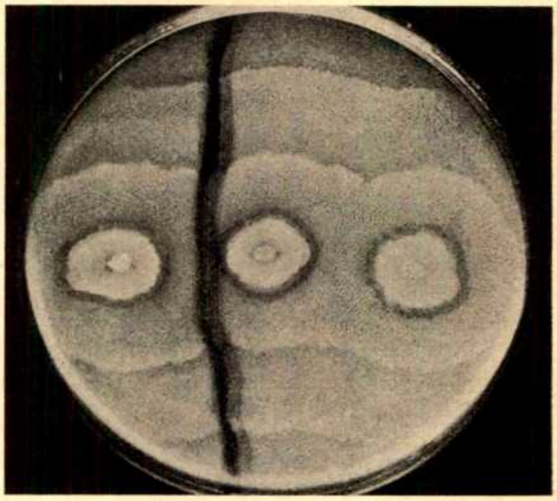

Fig. 1. Nutrient agar plate inoculated at one point on the left with strain 57(12/57) and at two adjacent points with strain 57. Incubated overnight at 37° C. Note how the inocula of strain 57 swarm into each other. The sharp line of demarcation between this spread and the swarming of strain 57(12/57) on the left denotes a positive Dienes phenomenon

Strains 57 and 13 can be transduced to streptomycin resistance by phages 12/57 and 34/13 propagated on streptomycin-resistant mutants of 57 and 13 respectively[4]. Lysogenic transductants possess all the properties of strains lysogenized with non-transducing phage.

Differences in properties of strains 57 and 57(12/57) and strains 13 and 13(34/13) are attributed to the presence of converting prophages 12/57 and 34/13. Conversion is in respect of phage-adsorbing capacity and possibly other antigenic changes as well.

Phages 12/57 and 34/13 are thus competent in transducing and converting systems. A similar position obtains with *Salmonella* phage *P*22. This phage has been extensively used in transduction experiments and can produce lysogenic conversion[4]. A possible difference is that this phage is capable of producing conversion in the vegetative state (phage conversion). No attempt has yet been made to investigate the latter possibility for the *Proteus* phages mentioned.

This work was aided by grants from the South African Council for Scientific and Industrial Research.

Elimination of Transmissible Drug-resistance by Treatment with Acriflavin

The first isolation of multiple resistant *Shigella* was reported by Kitamoto[1]. This was resistant to four drugs (r_4): streptomycin, tetracycline, chloramphenicol and sulphanilamide. *E. coli* r_4 was isolated in the epidemic of *Sh. flexneri* 3*a* r_4 (refs. 2 and 3). *Sh. flexneri* 2*a* r_3 and *E. coli* r_3 were also isolated in another epidemic, which were resistant to streptomycin, chloramphenicol and sulphanilamide[4]. *Citrobacter* r_4 and *E. coli* r_4 were isolated from a dysenteric patient after treatment with chloramphenicol[5].

From the epidemiological investigation of the multiple resistant *Escherichia* in the fæces of human beings[6], we have learned more about the multiple resistant *Shigella* and the general phenomena among Enterobacteriaceae.

Ochiai[7] and Akiba[8] reported that the multiple resistance was transmitted between *Shigella* and *E. coli* following mixed cultivation. This transmission is not mediated by transduction, transformation or filtrable agent, but by cell-to-cell contact[9,10] without regard to the polarity of *F* factor[11]. It has also been shown that the multiple resistance is transmitted between every genera of Enterobacteriaceae[12], whereas perhaps only 3–5 per cent of the strains of *Escherichia* would have given positive results in bacterial recombination.

Artificial elimination of the transmissible drug-resistance by treatment with acriflavin was carried out by Hirota's method[13].

The drug-resistant cells were inoculated into Difco brain-heart infusion broth containing sub-lethal concentrations of acriflavin (20 μgm./ml. for *E. coli* and 10 μgm./ml. for *Shigella*). After overnight incubation at 37° C., the cells were streaked on Drigalski's medium and the drug-resistance of each colony was tested. Heart infusion agar was used for assaying resistance to streptomycin, chloramphenicol and tetracycline. For assaying sulphanilamide resistance, semi-synthetic medium was used. It consists of 1 litre of medium *A* (ref. 14) agar enriched with 2·0 gm. casamino-acid, 10 mgm. tryptophan, 2 mgm. nicotinic acid, 10 mgm. thiamin hydrochloride and 2 gm. glucose. The results are shown in Table 1.

Table 1. FREQUENCY OF ELIMINATION OF DRUG-RESISTANCE BY TREATMENT WITH ACRIFLAVIN

Micro-organisms	With acriflavin treatment	Without acriflavin treatment
E. coli O–26 r_4	5/579 (0·9 %)	0/1,589*
,, r_3	15/547 (2·9 %)	0/881
,, r_1	0/579	0/364
Sh. flexneri 3*a* r_4	241/517 (46·6%)	0/1,198
,, r_3	0/375	0/1,177
,, r_1	201/583 (36·2 %)	0/1,116

r_4, resistant to streptomycin, chloramphenicol, tetracycline and sulphanilamide; r_3, resistant to streptomycin, tetracycline and sulphanilamide; r_1, resistant to tetracycline.

* Numerator, number of the drug-sensitive colony; denominator, number of the total colonies tested.

The drug-resistance of both *Escherichia* and *Shigella* were eliminated from the drug-resistant cells after treatment with acriflavin, and the frequency of elimination of the drug-resistance was higher in *Shigella* than in *Escherichia*. This fact is in agreement with the finding that the loss of the drug-resistance with *Shigella* was more frequent than with *Escherichia* after 6 months storage in cooked meat media. It was also found that all markers for drug-resistance were lost by treatment with acriflavin and the cells became sensitive to all drugs. The drug-sensitive cells thus obtained were not able to transmit the drug-resistance by mixed cultivation with other drug-sensitive cells.

GENETICS

Structural Mutations

THE premise that linear and continuous sequences of nucleotides in the genetic material (deoxyribonucleic acid (DNA) in most organisms, ribonucleic acid (RNA) in some viruses) specify corresponding linear and continuous sequences of amino-acids in the proteins, that is, the gene products of these organisms, is so fundamental to present-day thinking in the field of molecular biology that it has rightfully been referred to as the 'central dogma'[1,2]. Another premise, inherent in this dogma, is the principle of colinearity of the genetic map with the nucleotide sequence and the definition of a mutation as an alteration in this sequence giving rise in turn to an altered structure in the product proteins. The conclusion has therefore been implicit that every mutation must necessarily result in some alteration in a gene product.

It is the purpose of this communication to point out that this syllogism is neither logically sound nor necessarily reflective of the situation existing in Nature even on the basis of the fragmentary evidence at present available. It is conceivable that there exist regions in the genetic nucleic acid primarily concerned in the specification not of gene products but with nucleic acid structure itself. The structure here referred to is a 'tertiary' folding or other configurational alteration superimposed on the 'secondary' structure (the hydrogen-bonded helix). That such folding must exist in native genetic material is self-evident from a consideration of the dimensions of the heads of bacteriophages $T2$ or $T4$ (95×65 mμ)[3], as contrasted with those of the DNA contained therein were it to assume the fully extended, rigid, configuration demanded by the Watson–Crick hypothesis ($6 \cdot 3 \times 10^4$ mμ $\times$ 2 mμ). We[4,5] and others[6,7] have speculated that the secondary constituents associated with the DNA of these phages (internal protein(s)[7,8], polyamines[6,9]) may be concerned with the attainment and/or maintenance of this tertiary structure. The hypothesis of scattered regions concerned with tertiary structure has, however, other important consequences which can be tested.

It may be fruitful, for example, to institute a search for phage mutants, which possess *solely* an altered DNA, as a consequence of which they differ in their tertiary structure and in their DNA-protein interaction without, however, any significant alteration in the primary structure of any of the individual proteins specified by this DNA. It is possible that in $T2$ and/or $T4$ at least such mutations may already have been reported. One such might be the well-known class of acridine-resistant mutants[10,11]. On the basis of work by others[6,12–16] and investigations now in progress in our laboratories, it is likely that, in the dark under carefully controlled conditions, acridines in general and proflavine in particular exert a very specific inhibitory action on phage reproduction. This action occurs during that stage of maturation which is concerned with the integration of previously synthesized, structurally intact, and fully functional DNA with the structural phage proteins, mainly those of the head. The dye has no effect on the elaboration of either DNA (refs. 6, 15) or proteins[14,15] separately. The inhibitory effect may find its cause in the formation of a relatively strong and specific complex between the dye and phage DNA which is, however, rapidly and reversibly dissociated by dilution in the presence of normal phage constituents. Four predictions can then be made: (1) that a one-step proflavine-resistant mutant should be one possessing an altered DNA but normal proteins which allows maturation to proceed at concentrations of dye completely inhibitory to the wild type; (2) that it should be possible to detect this alteration in the DNA by comparing interactions of dye and DNA's from wild-type and mutant respectively by appropriate physical and chemical techniques, while phage proteins isolated from mutant and wild type should be identical in structure and indistinguishable by all criteria; (3) that a relatively large number of different mutants of this type should be isolatable and that these markers should be distributed more or less at random along the full length of the phage genome; (4) that multi-step mutants, which are resistant to higher levels of dyes, should manifest enhanced resistance by the criteria enumerated under (1) and (2).

Prediction (3) brings to mind another class of mutants. The *ht* (extended host range, turbid) markers studied and mapped very carefully by Baylor and her collaborators[16] appear to possess just such a distribution. Yet recent genetic and immunochemical work by Streisinger[17] and structural investigations by Williams and Fraser[18] make it apparent that, phenotypically, host-range and attachment to cells are manifested through just one species of protein, that of the tail fibres[19]. Once again those mutations may control not the structure of a protein *per se* but only that of the nucleic acid itself: in turn this structural alteration controls the interaction of the DNA with some protein(s), itself specified by quite a different section of the genome. Indications of this may be provided by Baylor's recent work on the stepwise and additive nature of these *ht* mutations with respect to their stability to incubation in buffer (Baylor, M. B., private communication).

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, March 20

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (joint meeting with the Utilization Section, at Savoy Place, London, W.C.2), at 6 p.m.—Mr. P. J. H. Rata: "Aluminium in Electrical Engineering"; Mr. A. D. Swanston and Mr. B. W. Towell: "Diesel Railway Locomotives"; Mr. T. E. S. Rickard: "Automatic Programmes for Hot Reversing Mills".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Miss Margaret F. Harker: "Photography in Education" (Cantor Lecture).

INSTITUTE OF METAL FINISHING (at Northampton College of Technology, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. U. F. Marx and Mr. D. Povey: "Zinc Plating from the Pyrophosphate Bath".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (joint meeting with the Ewell County Technical College Faraday Society, at the Ewell County Technical College, Reigate Road, Ewell, Surrey), at 7 p.m.—Dr. R. N. Haszeldine: "The Chemistry of Fluorine".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Sir William Holford: "Birth of a City".

Monday, March 20—Tuesday, March 21

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 10 a.m. daily—Symposium on "Fungicides in Agriculture and Horticulture".

Tuesday, March 21

INSTITUTION OF CHEMICAL ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Discussion meeting on: "Some Factors in the Safe Operation of Air Separation Plants".

INSTITUTION OF ELECTRICAL ENGINEERS, MEASUREMENT AND CONTROL SECTION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Self-Adaptive Control Systems" opened by Dr. J. H. Westcott, Dr. J. L. Douce, Dr. P. E. W. Grinsted and Mr. P. H. Hammond.

UNIVERSITY OF LONDON (at the Senate House, University of London, W.C.1), at 5.30 p.m.—Prof. W. Z. Hassid (University of California): "Transformation of Carbohydrates in Plants".*

UNIVERSITY OF LONDON (in the Gustave Tuck Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. D. A. Wright: "Thermoelectric Generation".* (Last of five lectures on "Generation of Electricity without the use of Rotating Machinery".)

ROYAL AERONAUTICAL SOCIETY (at 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. G. H. Lee: "Some Aspects of Buffeting".

Tuesday, March 21—Thursday, March 23

INSTITUTE OF METALS (at Church House, Great Smith Street, *London, S.W.1), at 10 a.m. daily—Spring Meeting.*

Wednesday, March 22

INSTITUTE OF PHYSICS AND THE PHYSICAL SOCIETY, COLOUR GROUP (in the Lecture Theatre of the British Lighting Council, Lancaster Place, London, W.C.2), at 3 p.m.—Mr. H. L. Gloag: "Some Principles of Good Colour in Buildings"; Mr. D. L. Medd: "Influences on the Use of Colour in Building in the United States of America".

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly London, W.1), at 5 p.m.—Prof. F. Hodson and Dr. G. C. Lewarne: "A Mid-Carboniferous (Namurian) Basin in Parts of the Counties of Limerick and Clare, Ireland".

BRITISH INSTITUTION OF RADIO ENGINEERS, COMPUTER GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Discussion on "The Future of High Speed Storage Systems".

INSTITUTE OF FUEL (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—Mr. E. Holmes-Smith, Mr. J. Lister and Mr. P. V. Liddell: "The New Wilton High-Pressure Cyclone Boiler".*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS AND SUPPLY SECTIONS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. Carruthers and Mr. D. L. Smart: "The Engineering Aspects of Plasma Physics".

INSTITUTION OF MECHANICAL ENGINEERS (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Sir Frederick Bartlett: "The Bearing of Psychology and Medicine upon Engineering" (James Clayton Lecture).

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Mr. J. Mauron: "Control of the Nutritional Qualities of Milk Protein".

Thursday, March 23

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Monsieur J. Prevost: "French Biological Work in the Region of Isle Kerguelen".

ROYAL AERONAUTICAL SOCIETY (at 4 Hamilton Place, London, W.1), at 6 p.m.—General H. Ziegler: "Problems of Short Take-off and Landing". (Fourteenth Louis Blériot Memorial Lecture.)

OIL AND COLOUR CHEMISTS' ASSOCIATION (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mr. H. C. Shellard: "Can the Climatologist *Help You?*"

Friday, March 24

ROYAL ASTRONOMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Geophysical Discussion on "Geodetic Uses of Artificial Satellites". Chairman: Dr. A. H. Cook. Speakers: Brigadier G. Bomford, Dr. R. d'E. Atkinson, Dr. A. P. Willmore and Mr. W. H. Guier.*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER IN PHYSICS—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (March 25).

ASSISTANT LECTURER (trained in electron microscope techniques) IN BIOPHYSICS in the Faculty of Medicine—The Registrar, The University, Manchester 13 (March 25).

PRINCIPAL (graduate of a British university, responsible experience in technical education, and preferably some industrial experience) OF THE FROME TECHNICAL INSTITUTE—Chief Education Officer, County Education Office, Trull Road, Taunton, Somerset (March 30).

HEAD OF THE DEPARTMENT OF MATHEMATICS—The Principal, Northampton College, St. John Street, London, E.C.1 (March 31).

IMPERIAL CHEMICAL INDUSTRIES FELLOWS (preferably with the degree of Ph.D. or equivalent research experience) to carry out original research in chemistry or physics, for a period not exceeding three years—The Registrar, University College of North Staffordshire, Keele, Staffs (March 31).

ASSISTANT LECTURER or LECTURER (preferably with an honours degree in mathematics) for work at the University Tidal Institute and Observatory—The Registrar, The University, Liverpool (April 4).

ASSISTANT LECTURER or LECTURER (with an honours degree in physical oceanography or physics, and prepared to spend several weeks each year at sea) IN THE DEPARTMENT OF OCEANOGRAPHY—The Registrar, The University, Liverpool (April 4).

LECTURER or ASSISTANT LECTURER IN BIOCHEMISTRY—The Registrar, The University, Leeds (April 4).

LECTURER (with a good honours degree, teaching experience up to degree level, and research experience) IN ZOOLOGY at the Nigerian College of Arts, Science and Technology, Zaria Branch—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (April 7).

RESEARCH BIOCHEMIST (with postgraduate research experience in the fields of protein chemistry or nutrition), to join a team investigating the effects of heat treatment on nutritional availability of the amino-acids in the proteins of foods—The Secretary, School of Agriculture, The University, Downing Street, Cambridge (April 7).

SENIOR LECTURER IN PHARMACY in the Science Department, Jamaica College of Arts, Science and Technology, Kingston—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (April 7).

LECTURER (with special qualifications in Latin American geography) IN GEOGRAPHY—The Registrar, The University, Leicester (April 8).

CHAIR OF PHYSICS—The Registrar, The University, Sheffield (April 15).

ASSISTANT LECTURER (with an honours degree in mathematics and preferably an interest in numerical analysis) IN MATHEMATICS—The Registrar, King's College (University of London), Strand, London, W.C.2 (April 17).

READER IN PHYSIOLOGY at London Hospital Medical College—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 17).

LECTURER IN PHYSICS at the University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, April 30).

LECTURER IN THE DEPARTMENT OF PHYSIOLOGY at Makerere University College, East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 30).

SENIOR LECTURER IN PHILOSOPHY at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, April 30).

UNIVERSITY ASSISTANT LECTURER IN ARCHÆOLOGY to give instruction in the archæology of the Anglo-Saxon and Celtic peoples—The Secretary of the Appointments Committee, Faculty of Archæology and Anthropology, Downing Street, Cambridge (May 15).

ASSISTANT OR ASSOCIATE PROFESSOR (with a Ph.D. and teaching experience) IN PHARMACOLOGY—Dr. H. G. Downie, Professor and Head, Department of Physiological Sciences, Ontario Veterinary College, Guelph, Ontario, Canada.

HEAD (physical chemist with outstanding qualifications and experience, and an original outlook) OF THE PHYSICO CHEMICAL DIVISION, to direct basic studies into the bulk properties of polymers and to initiate research in his own field of interest—The Director, Arthur D. Little Research Institute, Inveresk, Musselburgh, Midlothian.

LECTURER IN PHYSICS—The Clerk to the Governors, Northern Polytechnic, Holloway, London, N.7.

SENIOR TECHNICIAN (with experience in a physiological laboratory) to assist in work on lung function—The Secretary, Institute of Child Health, The Hospital for Sick Children, Great Ormond Street, London, W.C.1.

UNION CARBIDE POSTDOCTORAL FELLOW IN ORGANIC CHEMISTRY—Prof. R. C. Cookson, The University, Southampton.

THE UNDER-DEVELOPED TERRITORIES OF THE WORLD

IT is not surprising that in the debate in the House of Lords on January 25 on the North Atlantic Treaty Organization reference should be made to the recent report, *Increasing the Effectiveness of Western Science* (see *Nature*, 188, 879 ; 1960), and particularly to the proposal to create an Atlantic Institute of Science and Technology, a proposal which was strongly supported by Earl Jellicoe. Although Lord Carrington, who replied on the debate for the Government, agreed that the proposal merited serious consideration, he declined to commit the Government until the working group, on which Sir John Cockcroft is the United Kingdom member, had reported. While, however, there was other support in the debate, particularly from Lord Gladwyn, the Baroness Elliot and the Earl of Listowel, for the work which the newly formed Organization of Economic Co-ordination and Development of the North Atlantic Treaty Organization could do in co-ordinating all scientific activity, including the encouragement of the production of scientists and technologists, a notable, if not surprising, feature of the debate was the way in which these activities were related to the task of helping the under-developed territories.

This was seen as a moral responsibility, an important aspect of economic policy, and an essential element in the effective defence of the Atlantic Community. The Earl of Listowel, for example, welcomed the establishment of this new Organization as bringing Canada and the United States for the first time into full economic co-operation with other countries of the NATO group in Western Europe. This would facilitate the prior consultation and co-ordination of trade and economic policies that are essential if the West is to do more for the development of the under-developed countries, which still receive most of their capital investment and technical skill from the West. Lord Ogmore, in opening the debate, had stressed the need to increase assistance to the under-developed countries, and it was a key *motif* of the debate that technical assistance is an essential aspect of Western defence policy and in countering the social and economic challenge of Communism in those countries.

It is remarkable, therefore, that this theme should be absent when the Overseas Service Bill received its second reading in the House of Commons on January 24. The Bill was generally welcomed in the debate, and in moving the second reading the Colonial Secretary, Mr. Iain Macleod, stressed that when the Bill became law there would be a three-point structure in the Service, one of which was a vast scheme of technical assistance ; nevertheless, the debate generally was concerned rather with the other two points—the schemes of compensation and the public officers' agreement. Mr. Macleod could not add anything to his announcement in December that the Government is studying the establishment of a department or a ministry of technical aid or assistance, except that he hoped the results of this study would be available in a few weeks ; though he remarked that he regarded the Bill, which put heavy expenditure on the British taxpayer, as the most important proposal in relation to technical aid for the under-developed countries of the Commonwealth to be put before the House since the Colonial Development and Welfare Act.

Mr. Marquand, for the Opposition, agreed that the Bill contains far-reaching proposals, potentially of great value to the emerging countries, especially within the next five or ten crucial years of their development, and he thought that the implementation of its provisions would contribute to a world-wide extension of technical assistance and expert aid in the provision of the essential structure of development—the improvement of education, public health, agriculture, etc. Mr. P. Wall expressed the hope that Britain would go further than the Ministry for Overseas Aid which Mr. Macleod is at present considering, and endeavour to lay a foundation for the creation of an Overseas Service with interchangeable posting, to serve foreign countries as well as Commonwealth countries and provide administrators and technologists for United Nations organizations and for technical aid throughout the world. He believes there is a great future in this idea, and that development along such lines would ensure that the British genius for administration is not lost to the world.

Dr. Barnett Stross strongly supported the same idea, and, while concerned primarily with medical aid, suggested the creation of a Commonwealth Advisory Council to advise the Minister on medical and technical assistance generally. These suggestions received no comment from Mr. H. Fraser, the Under-Secretary of State for the Colonies, in replying on the debate. Although the debate was indeed concerned largely with the way in which the provisions of the Bill would affect existing officers of the Service, the importance of the contribution which Britain is making to technical assistance was fully recognized, and even the magnitude of the financial obligations which Britain will assume under the Bill was unchallenged except by Sir Kenneth Pickthorn. Mr. Macleod estimated the financial cost at possibly £150 million during the next ten years, and when to this are added the contributions under the Colonial Development and Welfare Acts of more than £25·5 million a year and of bilateral and multilateral assistance of roughly £140 million a year in 1959–60, the magnitude of Britain's effort will be appreciated.

The financial contribution, however, is only one aspect. The demand made on the scientific and technical resources of Britain, particularly in man-power, has also to be considered, and it is in this respect that the last report on *Colonial Research* was so disappointing. The Council for Scientific and Industrial Research, the Nature Conservancy and the Agricultural Research Council, in addition to the

Overseas Research Council, make important contributions to research overseas in various fields ; but there was no evidence in that report that the Overseas Research Council is attempting to provide a conspectus of the overall effort and the resources available. All the research councils are responsible to the Minister for Science, but the report provided no evidence that the Overseas Research Council is, in fact, doing anything that the Advisory Council on Scientific Policy could not do, or even to justify the change of name from the Colonial Research Council.

Difficult as they may be, the questions of co-ordination of effort and of communication are increasingly important, and it is as well to note that last year the Overseas Development Institute was formed to serve as a centre to which all those interested in the problems of developing countries could turn for information about the needs of those countries, and the action that is being taken to meet them. The Institute is intended to become a central office of information of this field generally, and also to serve as a centre in which those interested in particular aspects of these problems can meet and exchange views. Besides helping to make people dealing with such problems in government, academic, industrial or commercial undertakings aware of each other's activities, and to bring together those in the United Kingdom who are concerned with these problems and those who, in the developing countries themselves, have intimate knowledge of them, the Institute is intended to keep the public informed of what is going on in this field, of the needs of the developing countries and of what the industrialized countries can and should do to help.

The Institute is being financed by the Ford Foundation and by contributions from industrial and commercial undertakings in the United Kingdom, and it clearly envisages a wider field than the Overseas Research Council or even the Advisory Council on Scientific Policy could be expected to cover. Nevertheless, its formation points to a matter to which the Minister for Science might well give some attention and which should not be overlooked in the study now being made of the most appropriate means of channelling technical aid. The scale on which Great Britain is now contributing, financially and in trained man-power, to overseas development and welfare in the technical and scientific fields makes it imperative that that effort should be effectively co-ordinated and related realistically to the resources of the country, and to its other commitments and demands, as well as to the needs of the under-developed territories.

Particular reference was made to the Overseas Development Institute by Prof. P. M. S. Blackett in his Hinchley Memorial Lecture to the Institution of Chemical Engineers on February 15. Discussing "Science and Technology and the Developing Countries", he returned to a main theme of his presidential address to the British Association just over three years ago, and particularly to aspects of the general problem which were the subject of the symposium on "World Food and Population" in the Association's meeting at Cardiff last September, on which indeed Prof. Blackett drew considerably. It is essential, he said, in the first place, that a young and poor country, setting out on the difficult road of rapid social, economic and technological development, should have a clear idea of what are the right priorities for its investments ; and, like Lord Fleck at Cardiff, he pointed out that the under-developed countries must concentrate on a higher yield per acre, rather than, as in Western agriculture, on greater output per man. Until there is plenty of alternative employment in the factories, the saving of agricultural labour creates more problems than it solves ; in most parts of Asia the problem is really to devise new technologies which make man-power more efficient without much capital expenditure.

Since the improvement of agricultural yields is the most vital single step in much of South-East Asia, and in particular in India, and because the chemical engineer produces the plant required for the manufacture of the essential fertilizers, pesticides and selective weed-killers, Prof. Blackett considered this aspect of agriculture in the under-developed countries in some detail. The problem is fundamentally that of the application of known methods of production of chemical aids to agriculture and their use ; this involves much in the way of large-scale field-trials and experimental farms. Prof. Blackett also suggested that the resources of modern technology could be used to design plant, such as that for the fixation of nitrogen, which is economically more suitable for an under-developed country short of capital but with abundant labour. Detailed technological–economic studies of the possibilities of plants of various sizes ranging down to a small plant with the lowest possible capital cost might be very rewarding ; and if any could be brought below £70 per ton a year they might be of great value. The rate of growth of Indian fertilizer production is primarily limited not by lack of scientific knowledge or labour, but by lack of capital.

There is a further factor to consider. While the cost of the optimum size of plant is in the region of £30 million, in general, central governments alone can sponsor them. If, however, the cost could be reduced to £1 million or less, in some circumstances they might come within the scope of State or local governments, or even of private native enterprise ; this would be in line with the tendency for increasing stress to be placed on the development of moderate-scale industry right down to the village level. Further, the rapid spreading of technology in this way throughout a country has an important bearing on technical education, and Prof. Blackett suggested that the training given to the operatives could make a vital contribution towards raising the level of technical education.

Putting his theme into more general terms, Prof. Blackett advocated much more study by Western industrialists of the requirements of the developing countries for all kinds of production goods, from large- and small-scale plants to simple tools, taking account both of the latest technical developments and of the specific economic and social conditions of these countries. Further, he suggested that Western firms operating in under-developed countries should deliberately plan their educational or training facilities in excess of their own needs as a considered contribution to the general technical education of the country in which a particular firm is operating. This he intends should apply to the training of native personnel both in their own country and in the United Kingdom ; and from the trend of Mr. Anthony Tuke's remarks, in his chairman's address at the recent annual general meeting of Barclays Bank, on the needs of under-developed countries and the importance of contributing the investment which they require, it would seem that some such response may increasingly be expected.

There is, moreover, strong support to be found for Prof. Blackett's views in the presidential address which Prof. Abdus Salam delivered to the Pakistan Science Congress at Dacca on January 11. Prof. Salam, who referred to Prof. Blackett's address at Dublin in 1957, began by suggesting that acquisition of the requisite technological skills and investment of at least 5 per cent of the national income in the appropriate productive enterprises are the major pre-requisites of self-reinforcing growth. Japanese experience, he said, has demonstrated that the necessary technology is easy to acquire ; Russian experience that priorities on heavy industry accelerate the growth, and Chinese experience that labour is itself a form of capital. So far as Pakistan is concerned, Prof. Salam urged that a political group determined to eradicate poverty is a third prerequisite, and he thought that the new five-year plan reflects the emergence of such a group. The plan recognized the need for bold planning for agricultural development, for exploiting minerals and for heavy industry, and also that liberal provision for developing technological and scientific skills is the wisest investment a nation can make.

The plan aims at a 10–15 per cent capital investment, of which 3–4 per cent is required in foreign exchange and must come from the advanced countries in the form of long-term loans or gifts, and Prof. Salam readily acknowledged that this has involved real sacrifice on the part of those countries. The plan envisages the establishment of heavy industry, particularly steel, with an output of 400,000 tons, and the manufacture in place of import of fertilizers. The major effort, however, is in the provision of the necessary technical skills, including provision for an output of 7,000 technicians a year. Prof. Salam believes that 1961 may mark the beginning of a new era in Pakistan in respect of scientific research and training programmes. He recognized that the success of the Plan depends on some factors beyond Pakistan's own control, but Pakistan's scientists, he said, can none the less make an immediate and essential contribution to the elimination of poverty in Pakistan.

Fully as significant, however, as this consensus of opinion as to the needs and possibilities of technical aid, is the extent to which the whole problem is now being discussed objectively. Mr. A. Schonfield's lucid and comprehensive analysis, accompanied by some provocative suggestions, in his book, *The Attack on World Poverty*, published last year, dealt indeed with one particular aspect and stressed primarily the part that the United Nations should play. Although support for his views may have been somewhat shaken by subsequent developments in the Congo, his arguments as to the need for some re-organization, and in fact for effective co-ordination of the work of the numerous agencies, in spite of the difficulties involved, have been strengthened independently of the soundness of Mr. Schonfield's particular suggestions.

Perhaps even more significant, however, is the discussion of this problem in an article, "The Hungry Two-thirds", which appeared in the *Westminster Bank Review* of November, while earlier in the year the American Academy of Political and Social Sciences devoted the May issue of its *Annals* to a symposium of papers dealing with "International Co-operation for Social Welfare—A New Reality", a feature of which was the stress laid on the need for such technical assistance to be given on altruistic grounds and not in any spirit of competition or as part of a strategy in the defence of the Western world. This point was made again in an article by E. Rabinowitch, "The Atomic Age Doctrine : Common Efforts for Common Aims", which appeared in the *Bulletin of the Atomic Scientists* of September, and the subsequent issue of the same *Bulletin* contained an article by E. S. Prentice, "Significant Issues in Economic Aid for the Developing Countries", which summarized a report of the Stanford Research Institute on that subject. A second article in the same issue (October), by P. T. Bauer, on "Economic Development of Under-developed Countries" was at pains to stress the complexity of the whole problem and the vital importance of the institutional or administrative framework which governments alone can ensure for economic activities.

The need for some sort of master plan to co-ordinate the various types of aid being given to the developing countries, which now runs to something like £1,900 million a year, is one of the points made in the *Westminster Bank Review* article—and the need to diagnose thoroughly the problems peculiar to each country ; and it is also recognized that to increase the flow of international aid to the minimum of £1,000 million a year during the next ten years, which P. Hoffmann estimates as required from the West alone over and above the existing level, is not a complete answer. A steadier level of industrial demand for raw materials would of itself enable the developing countries to help themselves more easily. The emphasis in this article is on the political, economic and humanitarian reasons for overseas aid to the developing countries, but it nevertheless lends a good deal of support in general terms to the argument of Prof. Blackett and of Prof. Salam. Incidentally, it also stresses the desirability of channelling such assistance, so far as is possible, through international agencies, and it may be recalled that the World Federation of United

Nations Associations last year renewed its campaign for a ten-year international programme of world economic development.

Ideally, international distribution of technical and other forms of assistance is the right solution; but the objective appraisals of the situation now being made cannot ignore the plain fact that much of the aid distributed in recent years has been wasted, and even without the recent shocks to confidence dealt by events in Africa, the United Nations in its present structure can scarcely be regarded as competent to handle efficiently the flow of development capital and technical assistance on the scale now contemplated. Moreover, in any re-organization, the difficult problems of world government and the sacrifices of national sovereignty involved can scarcely be ignored, nor is it easy to find any recent grounds for supposing that many of the World Powers are prepared to make such sacrifices, however small. Nevertheless, these articles alone show that, at the technical level, the problems are being faced objectively, and President Kennedy's speeches have at least indicated that increasing economic assistance to the less-developed countries will be a central theme of foreign policy under the new American Administration. The United States can scarcely do otherwise than make some effort to ensure that its effort is effectively and efficiently channelled, nor are the voluntary agencies and foundations, like the Rockefeller Foundation, the Ford Foundation and the Carnegie Corporation, to the important contributions of which Dr. L. M. Hoskins directs attention in his contribution to the *Annals of the American Academy of Political and Social Science*, likely to be indifferent to this aspect.

Ultimately, the organization by which overseas aid is distributed, whether technical or financial, must be a matter for determination by governments, and that applies alike to the United Nations and elsewhere. It is not an easy problem to solve, nor is clear and constructive thinking the only condition of success. Widespread public understanding of the issues and the reasons for the sacrifices involved is no less imperative, and for that reason alone, the objective discussion of overseas aid in all its aspects cannot be too wide-spread. With special aspects scientists and technologists have their own particular and direct concern—Dr. E. F. Witte discussed the development of professional leadership in his contribution to the American Academy's symposium—and it is important that they should see that all the implications of such demands on the limited scientific and technical resources and man-power of Britain are fully and clearly understood; the general problem is one to which as citizens they can scarcely be indifferent. While their first concern may well be with the scientific and technical aspects, they have no less the opportunity and responsibility to see that the whole problem is objectively discussed, and to ensure that all the implications of aid on the scale now required, more especially in respect of international organization and administration, are fairly faced and resolutely and honestly handled.

Physical Methods of Organic Chemistry

Part 1. Edited by Arnold Weissberger. (Technique of Organic Chemistry, Vol. 1, Part 1.) Third completely revised and augmented edition. Pp. xii + 918.

Part 2. Edited by Arnold Weissberger. (Technique of Organic Chemistry, Vol. 1, Part 2.) Third completely revised and augmented edition. Pp. xii + 895–1797 + 21.

(New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959, 1960.) 184*s*. each.

IT was said, some forty years ago, of a prominent teacher of the then rapidly expanding subject of physical chemistry that he would attract to his laboratory many enthusiastic students by the epigram: "What you have called physics we here call chemistry". The forefronts of research in physics and chemistry have, since then, diverged, but it is evident to-day that twentieth-century chemistry has engulfed nineteenth century physics, for chemists and chemical technologists now make extensive use of exact measurements of the physical properties of different forms of matter.

With the widening of the scope of chemical science and the rapidity of the advancement of organic chemistry towards the biological sciences and the technologies of medicine, it is becoming more and more difficult for any chemist to have an adequate grasp of the principles underlying many types of physical measurements that he may wish to carry out, or of potentialities of available apparatus. It is therefore necessary for one to be able to find easily, on library shelves, authoritative treatises that review, in an up-to-date manner, the technological potential of both classical and modern physics. Since 1946 the series of reference volumes, edited by Arnold Weissberger and issued by Interscience Publishers under the general title *Techniques of Organic Chemistry*, has been recognized as a comprehensive, reliable, publication of this character, though why these books should, by title, be directed more specifically to organic than to inorganic chemists appears to be but a fad of the publishers.

Books of reference must be kept up to date, and now Vol. 1 of the series, that is, *Physical Methods of Organic Chemistry*, has been divided into four parts. Two of these parts have appeared so far in 900-page volumes costing more than £9 each. The periodic reprinting and modernizing of a standard reference work is essential, but in this case the wisdom of the American motto 'bigger and better' can be questioned, for a number of the chapters of these new volumes strike me as being obsolescent in that they deal with measurements of types that few chemists and fewer physicists would deem worth conducting to-day. Still, the book has been revised thoroughly throughout.

Part 1 contains new, short, chapters on automatic control, automatic recording, weighing (mainly a summary of formal theory) and determination of particle size and weight. These are of importance to technologists who need to service complex instruments. Older chapters, often expanded, deal with temperature measurement, calorimetry, determinations of melting and boiling points, of vapour pressure, solubility, viscosity, surface tension, osmotic pressure and with work on mono-layers. Part 2 contains one new chapter. This deals with X-ray microscopy, which, as the writer admits, has not yet much applicability to chemistry. The others deal with diffusivity, the use of the ultracentrifuge, with refractometry, with crystal measurement, with microscopy (in great detail), with X-ray crystallography (far too briefly) and with both electron and neutron diffraction. Few of these have been changed significantly in this edition, and indeed there is little of new import to be said about several of these techniques. However, it is rational to survey established experimental methods before dealing with others of more recent origin. Furthermore it is to be hoped that the forthcoming Parts 3 and 4, which are to deal, *inter alia*, with spectroscopy and both nuclear and paramagnetic resonance, will show that the overall expansion of the treatise is fully justified.

Too much of these first two volumes has evidently been written by physicists for chemists, and a common attitude seems to have been "here is what can be done with this type of measurement ; why you should wish to use it is not my concern". So much is the chemical approach missing that I noted quite a few instances in which no mention had been made of novel, yet significant, applications of old techniques, as, for example, uses of calorimetry and of interference refractometry in studying rapid chemical reactions, or of solubility and vapour pressure measurements in determining the purity of optically active compounds.

Many users may find the chapters too theoretical for their liking, but in this respect they would do well to note the dictum of one contributor that "the experimenter should know more of his subject than he needs to apply in attaining the particular accuracy of his present measurements". This caution was rightly followed by notes on the theoretical and experimental limitations of commercial instruments. Such sections throughout the book are well worth reading.

Every specialist who consults this book may find gaps in the treatment of his own topic, but one should be circumspect in not demanding too much of any treatise.

W. A. WATERS

HUMAN GROWTH

Human Growth

Edited by J. M. Tanner. (Symposia of the Society for the Study of Human Biology, Vol. 3.) Pp. vii + 120. (London and New York: Pergamon Press, 1960.) 30*s*. net.

THIS, the third volume published on behalf of the Society for the Study of Human Biology, is a record of the proceedings of one of the symposia which the Society convenes periodically (see *Nature*, 186, 19 ; 1960). The topics are many and varied and range from age-changes in primates and their modification in man, contributed by Prof. Adolph Schultz of the University of Zurich, to the effects of race and climate on human growth as exemplified by studies on African children. The latter studies were initiated by D. F. Roberts, University of Oxford, and are of particular significance because the samples were taken not from dwellers in the vicinity of administrative and urban centres, but from remote peoples in tribal and rural areas. They corroborate previous findings showing that African children differ from European children by a tendency towards lower weight for a given height.

Two contributions to the symposium should commend this book to all educationists. The first, by Dr. Roy M. Acheson, examines the effects of nutrition and disease on human growth, and brings ample experimental evidence to show that even a very brief insult can greatly retard the growth of a child. The other, by Dr. D. W. Boyne, is concerned with secular changes in the stature of adults and the growth of children, especially relating to changes in the intelligence of 11-year olds. Besides confirming that the intelligence of boys and girls varies with respect to one another at different ages, the author produces additional evidence to confirm that the intelligence of girls over the age of eleven has been improving relative to that of boys since before 1939. Whether this is due to real change in the innate intelligence or to change in the nature of the tests is not known. It is certain, however, that great progress in our knowledge of human growth has been made since Sir D'Arcy Thompson concerned himself with biological gradients and that, besides educationists, this book has much to interest anatomists, zoologists, anthropologists and medical practitioners.

DECISIONS, VALUES AND GROUPS

Decisions, Values and Groups

Vol. 1 : Reports from the First Interdisciplinary Conference in the Behavioral Science Division, held at the University of New Mexico. Edited by Dorothy Willner. (Sponsored by the Air Force Office of Scientific Research.) Pp. xxix + 348. (London and New York : Pergamon Press, 1960.) 80*s*. net.

THE foreword of this book is by Dr. Charles E Hutchinson, chief of the Behavioral Science Division of the Air Force Office of Scientific Research in Washington; the introduction is by Dr. Anatol Rapoport; and the preface is by the editor. It is divided into five parts : (1) Mathematical Models in Decision Processes ; (2) Conceptualizations and Designs for Research in Values ; (3) Theoretical Contributions to Small Group Research ; (4) Psychodynamic Patterns of Behaviour ; (5) Special Military Problems.

There are twenty-three independent papers, too many even to list. Only one paper necessitates an acquaintance with higher mathematics. It is entitled "Stochastic Choice and Subjective Probability". But the experiment conducted would be regarded as somewhat simple by a student of Prof. M. S. Bartlett's *Stochastic Processes*.

The significant characteristics of the book seem to be that decision processes and evaluative processes are regarded as essential scientific concepts. That is, no science can proceed without a system of values. But here lie the most difficult problems of human endeavour and "no quick-fixes or break-throughs" are claimed. Perhaps progress will be reported in Vol. 2.

The method of attack was to select a large team of highly qualified younger scientists from various behavioural sciences. Each was assigned a problem and they all attended an eight-week work-session during June 17–August 10, 1957, for interdisciplinary activity, that is, a kind of prolonged super-symposium. Such a method clearly has advantages, but there is the view that new ideas are produced by individuals and not by committees, the young research worker receiving daily inspiration and guidance in the laboratory of his chief. Both methods may be combined.

Dr. Rapoport writes: "The title of this volume reflects a delineation of areas of study which is different from the traditional delineations suggested by university departments. There is no university department concerned with either 'decisions', 'values', or 'groups'. Decisions are studied, of course, by psychologists, by political scientists, and by military strategists. A 'decision theory', however, should transcend these special content areas". Similarly, "Values are studied by philosophers, by economists, by psychiatrists and by anthropologists from different points of view and by different methods".

The change of pattern in air-force research during the past forty-five years is obvious. In the First World War it was largely sensory. Many of the problems were solved under the direction of two men working in close collaboration, the physiologist, General Wilmer of the United States, and the psychologist, Prof. Spearman of Britain. Thus, when more than seventy ace pilots were tested by means of a battery of ocular tests, it was found that most tended to do well. One exception, who did badly in one test, was a famous ace who lacked the ability to land his plane undamaged. He was always given another. In the Second World War, air force research was more concerned with intellectual capacities. At the present time, we have noted that research has embarked on the scientific study of values. Is it too sanguine a hope that this will eventually help to abolish war?

Ll. Wynn Jones

DISEASES OF ORNAMENTAL PLANTS

Diseases and Pests of Ornamental Plants

By Pascal P. Pirone, Bernard O. Dodge and Harold W. Rickett. Third edition. (An official publication of the New York Botanical Garden.) Pp. x+775. (New York: The Ronald Press Company, 1960.) 10 dollars.

THIS book follows very closely the plan of the second edition but has been brought up to date by the inclusion of the latest information concerning the control of pests and diseases. In addition, the authors have revised the nomenclature of the pathogens to accord with the present views of taxonomists and plant pathologists. It is also evident from the increased number of entries under the various host plants that many new pests and diseases have been recorded in the United States since the publication of the previous edition twelve years ago.

The book is divided into two parts. The first contains an introductory chapter on "Plant Diseases" in which the diseases are classified and described under symptoms and causes. This is followed by a chapter entitled "Bacteria and Fungi" (viruses are, rather surprisingly, omitted) in which the structure and classification of these organisms are briefly discussed. It is here that one finds (p. 39) the rather sweeping statement that "Recent improvements in staining techniques, however, have revealed one to three septa (cross-walls), showing the bacterial body actually consists of two to four cells". Likewise the observation (p. 42) that "The threads (hyphæ) of many fungi are composed of fundamental structural units, cells, found generally in plants and animals" is apt to be misleading as it stands. Mycologists will also, no doubt, be surprised to learn (p. 66) that "It should be understood, that every species of fungus now classed among the imperfect fungi will ultimately be found to be connected either with some ascomycete, basidiomycete or phycomycete". The third chapter is devoted to a general account of "Insect and Other Animal Pests" and is followed by one on "Control". This latter chapter contains much useful information on such topics as disinfection of seeds, bulbs, tools, clothing and hands; pasteurization of soil; fungicides, bactericides, insecticides and miticides; spreaders; and equipment. General advice on the choice, preparation and application of fungicides, bactericides and pesticides is also included.

The second part of the book consists of an account of the individual pests and diseases of particular host plants, which are arranged in alphabetical order according to their Latin names. This section appears to cover the subject very thoroughly, although there are omissions such as the failure to mention witches' brooms of *Carpinus* caused by *Taphrina* spp., but such instances are few.

Detailed comparison between the entries of the fungus diseases in this work with those of the second edition shows a number of omissions, but these would appear to be due to the authors having restricted themselves to diseases occurring in the United States. Sometimes, however, the wording in the second edition is such that one is not always clear whether the disease actually occurred in that country. There is one rather odd instance of an entry in the second edition under *Anemone* of rhizome-rot said to be caused by *Sclerotinia tuberosa* for which symptoms are given together with a full account of the fungus. The disease is said to be "irregular in its occurrence. It is found naturally on wild plants, but is not common in gardens around New York City and in cultivated plantings; it can be very destructive", all of which clearly implies its presence in the United States. In the third edition under review there is also an entry of rhizome-rot under the same host, but here the causative agents are said to be *Pellicularia rolfsii* and *Sclerotium delphinii*. No mention is made of a disease caused by *Sclerotinia tuberosa*.

In conclusion, it may be stated that the appearance of this third edition of *Diseases and Pests of Ornamental Plants* will be welcomed by plant pathologists and growers, especially those in the United States, although its usefulness is by no means confined to that country. Its faults are few and relatively unimportant since they are unlikely to cause serious inconvenience to the average person using this volume as a work of reference. It is attractively produced and very well illustrated. Furthermore it is printed in larger type than its predecessor which makes for easier reading.

Derek A. Reid

STREAMING OF INTERSTELLAR HYDROGEN IN THE VICINITY OF THE SUN

By Dr. R. X. McGEE, Dr. J. D. MURRAY and Dr. J. L. PAWSEY, F.R.S.

Radiophysics Laboratory, Commonwealth Scientific and Industrial Research Organization, Sydney

OBSERVATIONS of the 21-cm. hydrogen line have provided means for detecting the bulk movement of interstellar gas in our Galaxy. In addition to the well-known rotation about the galactic centre, Oort and Rougoor[1] have recently shown that the gas in the galactic disk, a few kiloparsecs from the centre, displays expansion at velocities of about 100 km./sec. It has been suggested by Kerr[2] that the outward movement may continue, with much reduced velocity, beyond the Sun. If this is so, where does the gas go? Does it stream outwards, above and below the disk? The results to be described here supply evidence for large-scale streaming of the gas in the vicinity of the Sun, but the observed flow does not conform with this simple picture.

The distribution of local neutral hydrogen has been discussed previously by Erickson, Helfer and Tatel[3] and by Davies[4]. We have recently completed a series of 21-cm. observations over the whole sky visible from Sydney with an aerial beam of 2·2° between half-power points and an *H*-line receiver of 48 channels spread at frequency intervals equivalent to 7 km./sec. in radial velocity about the natural line frequency. A full description of this equipment and the analysis of the observations is being prepared for publication.

One of the parameters extracted from the observations is $N_{\rm H}$, the number of hydrogen atoms in a line-of-sight column of 1 cm.^{2} section. It is derived from the integrated area of an *H*-line profile. Since the hydrogen is known to be concentrated in a thin layer (only a few hundred parsecs thick), most of the observations, except those near the Milky Way, will refer to gas in the vicinity of the Sun, that is, within a few layer thicknesses. A study of the distribution of $N_{\rm H}$ in galactic latitude showed it to be consistent with a general stratification parallel to the galactic plane in which a number of large clouds are embedded. These clouds include the Scorpius-Ophiuchus complex subtending some 3,000 square degrees, a large region in Gemini-Taurus-Orion, and its possible extension into Andromeda and Pisces. The examples mentioned are also characterized by *H*-line profiles the half-widths of which are less than 20 km./sec. Such evidence suggests that these local gas clouds are of a compact nature.

An approximate estimate of the neutral hydrogen density near the Sun has been made using: (1) average values of $N_{\rm H}$ at the different latitudes, and (2) the shape of the distribution in the z-direction (that is, perpendicular to the galactic plane) as derived by Schmidt[5]. The density is 0·46 hydrogen atom cm.$^{-3}$, which may be compared with 0·48 hydrogen atom cm.$^{-3}$, obtained by Westerhout[6], for the mean density between circles 8 and 9 kiloparsec. from the galactic centre. It would therefore appear that the Sun is situated in a representative region of the galactic disk.

Another parameter selected for study is the profile peak radial velocity. We have chosen the peak value since a great majority of the local profiles are single peaked and reasonably symmetrical. Thus the peak velocity gives a good representation of the gas velocity and, further, it may be easily and accurately read from the observed profiles. The velocities are referred to the local standard of rest.

The distribution of peak radial velocities is illustrated by the contour diagram of Fig. 1. The 'old' galactic co-ordinate system (Ohlsson) is used and, following convention, $l^{\rm I}$ and $b^{\rm I}$ designate galactic longitude and galactic latitude respectively. This is essentially a schematic diagram based originally on sample data analysis at intervals of 30° and 2° in $l^{\rm I}$ and $b^{\rm I}$, but afterwards checked at more frequent intervals. The contour interval is 3 km./sec. except for the zero velocity, shown in white, which includes -1, 0, $+1$ km./sec. values. Positive velocity regions are indicated by light grey and negative velocities by dark grey shading. In the Milky Way region an attempt was made to pick out only the contribution of the local gas, but uncertainties exist here due to possible inclusion of contributions from gas in other spiral arms. Radial velocities exceed 15 km./sec. in magnitude and reach maximum values of ~ 33 km./sec. in the hatched areas. Velocity values taken from the Leyden profiles[7] and Erickson *et al.*[3] have been used to augment the diagram in the region not visible from Sydney.

The striking feature of the velocity distribution is the extent of the areas of velocities of similar sign and magnitude. Two regions of positive velocity, one centred approximately on $l^{\rm I} = 10°$ and the other on $l^{\rm I} = 190°$, extend from the equator to galactic latitudes $\pm 40°$ over longitude ranges of more than 90° each. Regions of negative velocity lie between these at low latitudes. Negative velocities dominate the picture at high latitudes; the southern cap down to $b^{\rm I} = -40°$ is almost completely occupied by approaching gas, the northern cap has approaching gas together with a narrow sector near $l^{\rm I} = 150°$ of diffuse gas of various velocities including those of approach. The prevalence of negative velocities in the polar caps was noted by Erickson *et al.*[3].

The alternating positive and negative velocities in latitudes up to $\pm 30°$ are clearly associated with differential galactic rotation. It would be of great interest if, in addition, a general gas-flow pattern could be recognized. However, due to the lack of a measure of distance to the observed hydrogen, we cannot assign a particular velocity to be expected in a given direction due to differential galactic

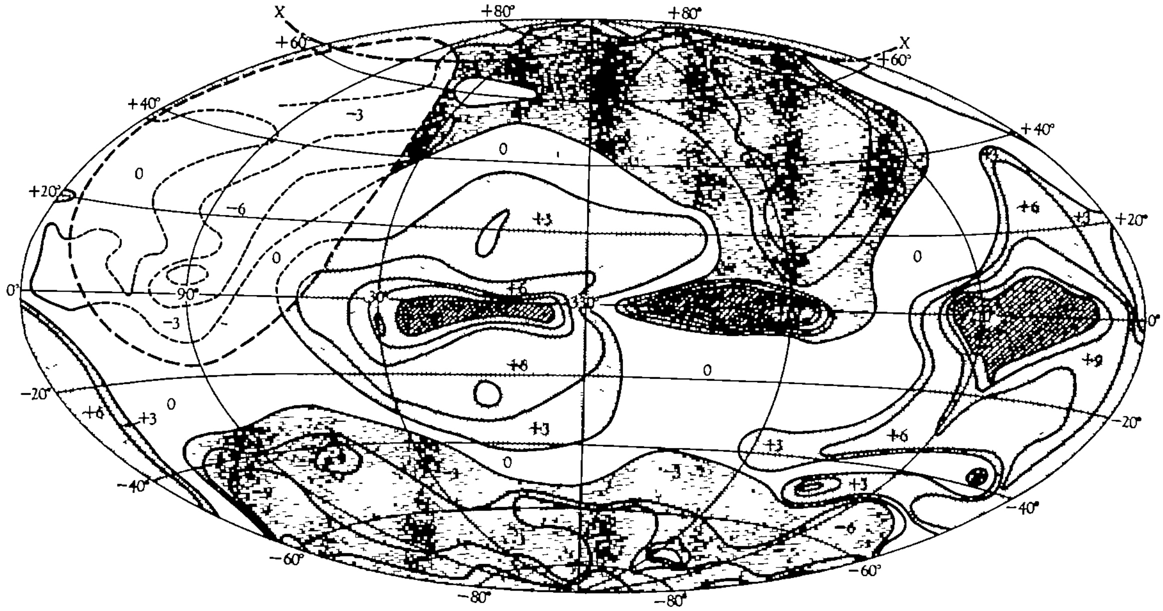

Fig. 1. The distribution of *H*-line peak radial velocities. The contour interval is 3 km./sec. Co-ordinates · 'Old' System, Galactic (Ohlsson). Light grey shading denotes regions of positive velocity, dark grey negative velocities, and white zero velocity (−1, 0, +1 km./sec.). Hatching denotes regions of velocity exceeding 15 km./sec. Diffuse gas of various peak velocities was observed in the region north of xx

rotation. But assuming the current rotational model and also that the Sun lies near the central plane of a stratified region of thickness $\leqslant 2z$ we can estimate an upper limit to the radial velocity, v_g, to be expected in a given direction (l^{I}, b^{I}), namely:

$$v_g \leqslant Az \cot b^{\mathrm{I}} \sin 2l^{\mathrm{II}} \cos b^{\mathrm{I}}$$

where A is Oort's constant (= 19·5 km./sec./k.parsec) and l^{II} the galactic longitude in the revised system in which the galactic centre is in the direction $l^{\mathrm{II}} = 0$ ($l^{\mathrm{II}} \approx l^{\mathrm{I}} - 327{\cdot}7$ at low latitudes). z has been taken as 0·11 k.parsec, Schmidt's estimate of the semi-thickness of the hydrogen layer to half density.

Examples of the derived curves are compared with the observed radial velocities in Fig. 2. Two quite definite results emerge. The first follows from the above equation in which the amplitude of the theoretical velocity curve falls to about 1 km./sec. above $|b^{\mathrm{I}}| = 45°$. In effect, then, the observed velocities in high latitudes are scarcely influenced by differential galactic rotation and hence local in-streaming of the gas is indicated.

The second result is due to the fact that, no matter how inaccurate the value of z may be, the radial velocity due to differential rotation in circular orbits must pass through zero at the longitudes of the galactic centre and anti-centre (327·7° and 147·7° respectively). The existence of observed positive velocities in these directions, and in directions where the model predicts negative velocities, emphasized in Fig. 2 by the thick segments, means that here the gas has an additional outwards motion. We consider that at low latitudes the other differences between observed and predicted values are within the uncertainty in interpretation.

Referring to Fig. 1 we conclude that at high latitudes, in the range $90° > |b^{\mathrm{I}}| > 40°$, neutral hydrogen is definitely flowing in from above and below at approximately 6 km./sec. at all longitudes. At low and middle latitudes the gas is flowing away

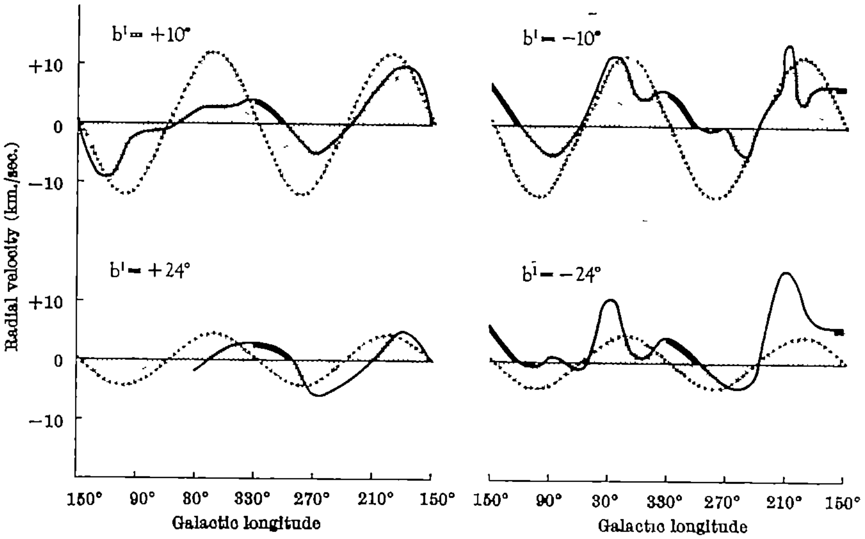

Fig. 2. Examples of curves of radial velocity against galactic longitude. The full curves show observed velocities. The shaded areas give the range of predicted velocities due to differential galactic rotation. The thickened segments of the observational curves indicate definite discrepancies between observation and these predictions

from the Sun in the general directions of the galactic centre and in southern latitudes near the anti-centre at approximately 6 km./sec.

We describe these motions as streaming, but we cannot tell if they are peculiar to our vicinity or whether they form part of a general circulation. Quantitatively, for the polar caps, combination of the velocity of inflow of 6 km./sec. with an estimated density of about 0·5 hydrogen atom cm.$^{-3}$ leads to a rate of inflow of about $10^{-7} M_{\odot}$ (solar mass) per square parsec per year. If this flow is general over a substantial part of the galactic disk, the amount of gas flowing in over a ring of 1 k.parsec width at the radius of the Sun would be several solar masses per year, so that the quantities of hydrogen involved would be sufficiently great to make the phenomenon a major feature of galactic dynamics.

A HYPOTHESIS CONCERNING THE MECHANISM OF GENE ACTION

By Dr. CARL C. LINDEGREN

Biological Research Laboratory, Southern Illinois University, Carbondale, Illinois

Components of a Gene-System

It is usual to think of the gene as a particle located on the chromosome; but the phenomena associated with the action of a given gene occur in various places throughout the cell and should be considered to comprise a system which I shall designate the gene-system. The gene-system includes at least three separable entities: the receptor, located on the chromosome at the place usually spoken of as the locus of the gene, the transmittor and the effector. This discrimination is based on the fact that the gene is on the chromosome, and the enzyme which the gene controls is almost certainly synthesized in the cytoplasm, since the cytoplasm is the principal site of protein synthesis.

A Gene-System in Saccharomyces

The gene-controlled synthesis of an enzyme, such as melezitase[1,2], in the yeast cell, is initiated by exposure of the cell carrying the gene to various short-chain α-glucosides. In cells carrying the gene controlling the synthesis of melezitase, each of the different α-glucosidic inductors initiates the synthesis at the locus of the gene on the chromosome. The initiatory event results in the production of an enzyme which appears to have the same characteristics irrespective of the inductor. The mechanism which connects the induction at the locus with the final synthesis of enzyme in the cytoplasm is designated the transmittor. Melezitase (which is not present in an unadapted cell)[2] splits many relatively short-chained α-glucosides. It is induced by the five different α-glucosides, namely, turanose (*T*), maltose (*M*), sucrose (*S*), α-methyl-glucoside (*G*) and melezitose (*Z*). The letters *TMSGZ* are used to designate the dominant allele of the gene[3]. Unadapted cells require more than 1 hr. to accumulate detectable amounts of enzyme. The enzyme induced by any one of the inductors acts on all the other inductors and a few other short-chain α-glucosides[2,4] without an induction period, that is, without further adaptation. Because the different inductors seem to initiate the production of the same enzyme, it is inferred that both the transmittor and the effector respond to a stimulus initiated at the receptor, resulting in the production of a single uniform product, irrespective of which one of the five inductors acted as the inducing agent. Any inductor can activate the effector; the effector reacts non-specifically with respect to the specific inductor. These facts led to the hypothesis that the receptor[5], in the nucleus, which responds to a specified variety of inductors, and the effector, in the cytoplasm, which acts uniformly irrespective of which of the specified inductors initiates the action, must be connected by a transmittor.

Anatomy of the Receptor

Some ideas about the anatomy of the receptor have been suggested from the study of a series of multiple alleles which occupy the *TMSGZ* locus. The multiple alleles are distinguished from each other by their different abilities to respond to the five different inductors. Because there are five separable characters, thirty-two different possible multiple alleles might be expected if each character were expressed independently of the other four characters[3]. One allele, *TMSGZ*, responds to any one of the five inductors by the production of enzyme. At the other extreme is the totally recessive allele, designated by five dashes (– – – – –), which does not respond to any of the five inductors. Five other partially recessive alleles of the locus have been discovered: *TMSG–*, *TMS–Z*, *TMS– –*, *TM – – –*, *T– – – –*. Cells carrying these alleles respond to the inductors indicated by the capital letters but are incapable of responding to the substances indicated by the dashes. The limitation of the number of alleles proves that the characters are not expressed independently of each other. The fact that only one allele is incapable of responding to turanose as an inductor and that this allele is also incapable of responding to any other inductor indicates that the turanose character is fundamental to the receptor. This suggests that an injury to the locus which renders it incapable of responding to turanose will impair the capacity of the gene-system to respond to any other inductor. The limitation of the number of alleles suggested the hypothesis that the receptor is a conformation composed of at least five different overlapping patterns each composed of one or more elements[5,6]. Each of the patterns is assumed to fit one of the five inductors and to act as the specific receptor for that particular inductor. The elements of a pattern are assumed to form a template, or a reverse model, or a 'cast', of the inductor. Deformation of any element of a pattern may result in the inability of the particular inductor, for which the pattern is a receptor, to fit the inductor. The various patterns of the total conformation are assumed to overlap in such a manner that the turanose pattern is a component part of each of the other patterns, and it is assumed that injury to an element of the turanose pattern will make it impossible for any of the inductors to fit the conformation. But deformation of an element comprising the melezitose pattern will not prevent the other four inductors from fitting the conformation and bringing forth the production of enzyme.

Mutation by Ultra-violet Rays

Analysis of the mutagenic effects of ultra-violet rays on *TMSGZ* suggests that each pattern has a specifically different sensitivity to ultra-violet rays[3]. When *TMSGZ* is subjected to ultra-violet radiation the different alleles are recovered from among the survivors with approximately the following frequencies: *TMSG–*, 8 per cent; *TMS – –*, 4 per cent; *TM – – –*, 2 per cent; *T – – – –*, about 2 per cent; and – – – – –, less than 1 per cent. If one assumes that *TMSG –* results from injury to the *Z* pattern, the results indicate that the *Z* pattern is more sensitive than any other pattern. Likewise, if one assumes that – – – – – is the result of injury to the *T* pattern, the results indicate that the *T* pattern is more resistant than any other pattern. The *M* and *S* patterns are inferred to be about equally sensitive, but more sensitive than the *T* pattern. The *G* pattern is about half as sensitive as the *Z* pattern. The sensitivities of the different patterns may be ranked in the following ascending order: *T, M, S, G, Z.*

Gene-Conversion

Multiple alleles are also produced by gene-conversion. The multiple allele, *TMS–Z*, was recovered from cross-breeding experiments presumably as the result of gene-conversion[1]; it was not discovered among the survivors of ultra-violet irradiation. This suggests that the mutation of *TMSGZ* to *TMS-Z* (which involves injury to the *G* pattern without injury to the *Z* pattern) may occur in a heterozygote but is not commonly produced by ultra-violet radiation. A complete series of alleles indistinguishable from those produced by ultra-violet irradiation was recovered by tetrad analysis of heterozygotes. It was inferred that this series of alleles had been produced by gene-conversion[7].

X-ray Mutations

A third procedure for producing the different multiple alleles is X-irradiation. In contrast to ultra-violet-induced mutation, treatment with X-rays has produced only two types of mutants from the *TMSGZ* dominant allele; namely, *TM – – –* and – – – – –[4]. Although ultra-violet rays may destroy one pattern without affecting contingent patterns, the results suggest that the effect of X-rays may be 'spread' over several contingent patterns. For example, the *TM – – –* mutant might result from a 'hit' in either the *G* or the *Z* pattern which spreads to include the *S* pattern. The – – – – – mutant (which is characterized by damage to the *T* pattern) might be the result of a 'hit' which spreads to the *T* pattern from as far 'away' as the *S* pattern. Many lethal mutants were probably produced by X-rays but were not recovered. The mutants which survived and were recovered might have been produced by impacts of low energy. These inferences are consistent with the generally held view that ultra-violet rays are much less devastating in their mutagenic action than the X-rays.

Gene-Transformation by Substrate

Gene-transformation is defined as controlled mutation produced by a chemical reagent. In the preceding experiments, mutations from normal to defective were described[3]. Several reports from this Laboratory have concerned controlled reverse mutation from defective to normal by exposure of cells to specific carbohydrates[8,9]. Exposure of different partially recessive members of the *TMSGZ* series of multiple alleles to various specific substrates (especially to melezitose) has effected reverse mutations from various partial recessives (*TMSG –*, *TMS – –*, *TM – – –*, *T – – – –*) to *TMSGZ*. The partially recessive alleles are all stable when carried in culture on glucose. That is, when glucose is the only carbohydrate in the culture medium, and the cells are not exposed to any other sugar, the cultures can be carried indefinitely in sub-culture without encountering any alleles except those of the original culture. Because of our experience with the mutagenic effect of saccharides on yeast, cultures in this Laboratory are never returned to the stored 'stock' cultures after having been grown on any sugar except glucose. The stock cultures are all grown on a complete natural medium of peptone and yeast extract. Mutations at the *TMSGZ* locus occur when cultures carrying the 'partially' recessive alleles *TMSG –*, *TMS–Z*, *TMS – –*, *TM – – –* and *T – – – –* (excluding the totally recessive – – – – – allele) are planted densely on an agar plate containing melezitose. For example, if 10^6 *TMSG –* cells are spread on an agar plate containing melezitose, a small number, approximately 1×10^{-7} *TMSGZ* cells, are recovered. Thus exposure of the partially recessive *TMSG –* culture to melezitose transforms the *TMSG –* gene from a partially recessive to the *TMSGZ* dominant. The other partially recessive alleles also mutate to *TMSGZ* in the same circumstances. All the different partially recessive alleles (*TMSG –*, *TMS – Z*, *TMS – –*, *TM – – –*, *T – – – –*) when exposed to melezitose mutate to the same allele and only to this allele—the totally dominant *TMSGZ*[10].

I suggest that the receptor is a protein folded on the surface of the chromosome. The phenomenon of melezitose-induced reverse mutation suggests that, in the presence of melezitose, a defective element (which is inferred to be a 'false' fold in the receptor-protein) becomes folded into a functional pattern in the 'new' receptor protein, thus correcting the defect. It appears that, in the absence of melezitose, each receptor-protein folds in the same manner its 'parent' protein had originally folded and that the folding pattern of each of the alleles is hereditary.

The fact that melezitose is a chemical substance which induces a specific mutation specifies it as a transforming agent.

The 'Respreading' Experiment

The fact that reverse mutations from *TMSG* – to *TMSGZ* do not occur at a detectable rate on glucose supports the view that melezitose is the mutagenic agent. Confirmation of this view is derived from Newcombe's "respreading" experiment[11]: if a dense suspension of cells is planted on a melezitose-agar plate and the cells are respread four hours later (after about 2 divisions have occurred) the number of revertant colonies appearing on the respread plate is statistically equivalent to the number which appears on a control melezitose-agar plate on which the cells were not respread. If respreading is delayed for 10 hr. (after each colony contains many more cells) an increase in *TMSGZ* colonies is observed. The respreading experiment proves that the fermenter cells were not originally present among the glucose-grown cells planted on melezitose-agar. Hence, the reverse mutations were produced by contact with melezitose. (The failure to obtain an increase in the number of fermenter colonies if respreading is performed within 4 hr. is not due to the failure to break up clusters of cells. This was demonstrated by respreading mixtures of fermenter and non-fermenter cells at 4 hr. When plates are inoculated with artificial mixtures, an increase in the number of fermenters consistent with the number of divisions which has occurred is always observed, indicating that even the small clusters of cells break up easily[8].) These observations do not exclude the possibility that some undetectable reverse mutations may occur at a very low rate. For example, if the rate were 1×10^{-12}, it would be difficult to sample a sufficient number of cells to make the test. Replica plating experiments[3] showed that the 'spontaneous' frequency of back mutation of the partially recessive allele is less than 1×10^{-8}.

The fact that no change in the number of resistant colonies occurs in the first 4 hr., during which at least 2 divisions have occurred, indicates that the mutation does not usually occur in any of the four cells which are produced during the first 2 divisions. The mutations appear to be delayed until after several generations of contact with the mutagenic carbohydrate, suggesting that growth of the cell is essential to the occurrence of the mutation. Since it is inferred that the mutation is due to a change in the folding of a protein-receptor, these results suggest that the change can only occur during the formation of a 'new' receptor and that the 'old' receptor remains unchanged, even in the presence of melezitose.

The fact that melezitose has the capacity to direct the mutation of a defective into a normal gene means that melezitose is a transforming agent. This experiment shows that agents other than nucleic acids have the capacity to produce gene-transformations.

Synergistic Effect of X-rays and Melezitose on Gene Transformation

Cells carrying the totally recessive allele, designated by 5 dashes (– – – – –), do not respond to any of the five inductors by the production of the adaptive enzyme, melezitase, and are refractory to the mutagenic effect of substrate in the absence of auxiliary treatment. When the totally recessive allele is spread on an agar plate containing melezitose, revertant colonies are not recovered. If, however, the culture is treated with X-rays before spreading on melezitose-agar a few dominant *TMSGZ* colonies are recovered[5,10]. When the frequency of recovered colonies was plotted against the X-ray dose, it was found that the mutagenic effect was produced by a single 'hit'.

Size of an Element

The results were used as the basis for calculating the size of the 'target'[12] and the calculation indicated that the element had a molecular weight of from 15 to 60. The determination of target size at a level much below that of a single nucleotide indicates that this mutation is due to changes in items smaller than single nucleotides, and, hence, that the 'element' is not a single nucleotide.

Refractory (Stable) Nature of the *T* Pattern

The ultra-violet-ray experiments dealt with the induction of 'loss' mutations (*TMSGZ* mutated to – – – – –; the '*T*' pattern from '*T*' to '–'); conversely, the X-ray-melezitose experiments involved the 'gain' mutation from – – – – – to *TMSGZ*, presumably by remodelling of the '*T*' pattern from '–' to '*T*'. X-rays seem to alter the turanose pattern in some way which permits melezitose to induce the mutation from – – – – – to *TMSGZ*, in which the turanose pattern is changed from one which does not fit turanose to one which does. The X-ray experiments showed that the – – – – – allele was refractory to the transformation (– to *T*) by substrate alone and that a previous treatment with X-rays was required to produce the change. The turanose pattern is also more resistant to mutation by ultra-violet rays from *TMSGZ* to – – – – – (*T* to –) than any of the other patterns – –. The turanose pattern resists mutation in either direction.

The turanose pattern appears to be the basic pattern, and all the other patterns seem to have the turanose pattern as an essential component. If the ability to ferment turanose were the only criterion by which the genotypes of the locus were identified, this locus would appear to be extraordinarily stable and of extremely high penetrance. The fruitfulness of the present inquiry has arisen from the fact that many different means were available for identifying the different multiple alleles.

Characteristics of the Enzyme produced by *TMSGZ*

Cells containing melezitase act on the five inductors immediately at different rates. In general, the adapted cells act most rapidly on turanose, next most rapidly on maltose; the rate on sucrose is slightly lower. The rates on alpha-methyl-glucoside and melezitose are much lower than the rate on sucrose. Although individual determinations are subject to some error, the lowest rate appears to be that on melezitose. This is true whether whole cells or cell-free preparations are tested; the similarity between cell-free preparations and whole cells excludes the possibility that the differences in rates might be due to differences in the permeability of the membrane to the different saccharides.

The Permeability Barrier

Data from two sources revealed that the different inductors enter the cell at the same rate. (1) Data on oxygen absorption of a *TMSGZ* culture in solutions of the different sugars supported the view that the different rates of fermentation were not due to different rates of entry[4]. When curves, describing the rates of oxygen absorption of the cells undergoing adaptation to the sugars in different Warburg vessels, are extrapolated, they intersect on the time axis at the same point. Thus, the period elapsing from the time at which substrate is added to the time at which the cells respond is the same for the different substrates, indicating that the time required to pass through the permeability barrier is the same irrespective of the inductor. But the rate of fermentation of each substrate is characteristically different and this is inferred to be due to characteristic differences between the rates at which the same enzyme splits the different substrates. (2) Data from cell-free preparations (in which permeability barriers have been destroyed) confirmed the fact that the different rates after adaptation are due to the differences with which the induced enzyme acts on the different inductors.

A POSSIBLE MECHANISM OF GENE ACTION

Parallels between the Enzyme and the Receptor

It is generally held that the enzymes which act in the cytoplasm, and are produced in the cytoplasm. are proteins. Thus, the enzyme, melezitase, which is assumed to be a protein, acts with different rates on the different inductors, cleaving each inductor at a specific and characteristic rate. The rates may be arranged in the descending order: turanose, maltose, sucrose, alpha-methyl-glucoside and melezitose. There is a significant parallel between: (1) the activity of the enzyme toward the different substrates and (2) the sensitivity of the different patterns to ultra-violet rays. The correlation between these two different phenomena invites the hypothesis that both the receptor of the gene-system and the enzyme are folded proteins which mimic the topology of the surface of the carbohydrate inductors. The capacity of the single *TMSGZ* conformation to fit the five different inductors is inferred to be due to the relationships of the basic turanose pattern to the overlapping and partially superimposed patterns of the other four inductor molecules. The argument that the receptor surface is *not* deoxyribonucleic acid (DNA) is supported by the fact that nucleic acid is not needed to transform the defective surface into a functional surface since the trisaccharide, melezitose, can transform any of the impaired or damaged surfaces, presumably by acting as a model on which a new receptor surface is formed.

Relation of DNA to the Locus of the Gene

The hypothesis that the receptor is a folded protein does not rule out the essential involvement of nucleotides in the gene-system. It is proposed that the receptor 'fits' the chromosome by being engaged to the coded nucleotides, either RNA or DNA, which comprise the chromosome at the specific locus of the gene. This theory rejects the view that the chromosome is simply a double helix of DNA. It proposes that the chromosome is a many-stranded structure with both protein and RNA associated at the locus. It also proposes that if coding of the nucleotides has significance, some single strands of DNA must be free to react at the locus of the gene. On this theory, the specific variations of the outer surface of the receptor depend partially on the contact of the inner surface of the receptor with the single strands of coded nucleotides, and the integrity of the receptor depends on contact with these coded nucleotides. Minor deviations in the shape of the receptor which depend simply on folding of the protein may be independent of the nucleotide sequence and may be corrected by refolding the protein in the presence of the carbohydrate inductor. (These are the partially recessive mutations which can be induced to undergo mutation to normal by treatment with the inductor.) But if the nucleotides are rearranged, the surface of the conformation, and hence the patterns which fit the inductor, are disturbed. Reactions which affect the synthesis of purines or pyrimidines could produce gene mutations by altering the 'seat' on which the receptor is folded. The coded sequence of the nucleotides at the locus is essential to the maintenance of the conformation characteristic of the receptor surface because it would determine the type of folding which will occur, thus affecting the outer surface of the receptor. The theory is consistent with the view that changes in the nucleotide arrangement of the chromosome could lead to mutation.

On this hypothesis DNAase should destroy transforming principle, since it would remove the DNA 'seat' on which the protein is folded and maintained in the normal conformation. Re-arrangement of nucleotides in the chromosome would tend to change a normal gene into a defective gene.

The theory proposes that the receptor-protein has: (1) an outer (functional) surface and (2) an inner surface in contact with the nucleotides. The fact that the partially recessive alleles are transmitted unchanged from generation to generation suggests that irregularities in the folding of the receptor-protein, such as those, for example, which differentiate *TMSGZ* from *TMS – –*, are transmitted from generation to generation. This phenomenon suggests that hydrogen bondings within the folded protein are transmitted from generation to generation. It is proposed that this effect is produced by the folding of the 'new' protein produced at each 'new' generation on the lateral surface of the 'old' protein. In the presence of melezitose the receptor-protein occasionally folds on both the nucleotide surface and the melezitose surface and the irregularities in folding which produced the partially recessive alleles are 'corrected' and *TMSGZ* is produced.

Relation of Synapsis to Transformation

I have discussed elsewhere[13] the importance of DNA in homologous synapsis and proposed that the DNA component of the transforming principle ensures that the 'transforming agent' will be fitted into its proper position in the chromosome by combining with the homologous complementary single strands of DNA on the chromosome.

The Particulate Gene

This theory implies a return to the theory of individual particulate gene and rejects the idea that genes are continuous[14]. The coded nucleotide serves: (1) to hold the receptor-protein in place; (2) to form a base on which the protein can fold in such a way that a functional conformation will result; and (3) to ensure the precise homologous synapsis which will prevent non-reciprocal or unequal crossing-over. On this theory, the gene is defined as a 'linear section of the chromosome capable of accommodating one species of a variety of closely related (allelic) receptors'. Steffensen's[15] theory of crossing-over, which states that the chromosome is a continuum in which nucleic acid segments are held together by Ca bonds, and that crossing-over occurs only at these Ca bonds, is consistent with the theory.

Crossing-over versus Other Kinds of Recombination

Crossing-over is defined as exchange occurring between chromatids by breakage and reunion which is usually reciprocal and is assumed to occur at the Steffensen bonds. Other kinds of recombinations may be due to gene changes by: (a) substitution, deletion or chemical alteration of nucleotides; (b) gene-conversion, gain or loss or alteration of receptor-protein; or (c) transduction. A critical discrimination between crossing-over and recombination due to causes other than crossing-over can be made only if tetrad analysis is available. Most of the low-frequency recombinations which have been revealed by viral and microbial genetical analysis are almost certainly not due to crossing-over.

Function of the Nucleolus

On this theory one element of the transmittor of each gene-system is the moiety of RNA[16] (the template) which passes from the nucleus into the cytoplasm to effect the synthesis of enzyme in the cytoplasm. The nucleolus is a temporary organelle appearing in a restricted region of a chromosome during the interphase between nuclear divisions. It is reasonable to suppose that the nucleolus is an organelle in which RNA is processed during its passage into the cytoplasm. The nucleolus affords an isolated site in which RNA could be altered without interfering with other reactions, especially reactions that occur in the cytoplasm. Thus the nucleolus would be an important component of the transmittor, and all that is known concerning the function of RNA in the synthesis of protein is consistent with the theory in explaining the synthesis of enzyme.

Gene-Conversion and Delayed Mutation

This theory suggests that the mechanism of gene-conversion might be different from that of transformation. Conversion from defective to normal, or *vice versa*, might occur in the heterozygote without breakage of the DNA strand of the chromosome and without involving crossing-over. It is proposed that conversion could be effected by the transfer of receptor-protein from the locus on one chromosome to the corresponding locus of its homologous partner. The stability of non-reciprocal recombinants in yeast heterozygotes[17] and the photo-reversibility of non-reciprocal recombinants[18] offer evidence in support of this hypothesis. Transfer of receptor-protein between homologous loci could produce the non-reciprocal recombinations detectable by tetrad analysis which are characteristic of gene-conversion. The stability of the multiple alleles produced by gene-conversion at meiosis suggests that only a few receptors are present on the meiotic chromosome. But it would be reasonable to suppose that many receptors are present at each locus of the mitotic chromosome. This could explain delayed mutations, because if a large population of receptor-proteins at a locus were predominantly normal, with only a few defective, many multiplications might occur before a gene containing predominantly defective receptors were produced. Variations in the penetrance, expressivity or potency of genes (or high rates of mutability) might be due to variations in the population of receptor-proteins at a locus.

Significance of the Parallel between Enzyme and Receptor

The new phenomenon revealed by the study of the *TMSGZ* alleles is the parallel between the properties of the receptor on the chromosome and the properties of the proteinaceous enzyme in the cytoplasm. The *TMSGZ* gene-system is identified by five characteristics: the ability to hydrolyse the five sugars—turanose, maltose, sucrose, α-methyl-glucoside and melezitose. Treatment of the cells with ultra-violet rays shows that the different patterns of the receptor vary in sensitivity to ultra-violet rays: the most sensitive pattern is the melezitose pattern; the most resistant pattern is the turanose pattern. The different patterns can be arranged in descending order according to ultra-violet sensitivity: *T*, *M*, *S*, *G* and *Z*. The changes in the gene are transmitted according to the rules of Mendelian heredity, proving that the experiments on sensitivity to ultra-violet rays pertain to the effects on the receptor located on the chromosome. But the characteristics of the enzyme involve events in the cytoplasm and the enzyme exhibits certain characteristics which parallel those of the gene. The substrates can be arranged in the following descending order according to the activity with which the enzyme acts on them: turanose, maltose, sucrose, α-methyl-glucoside and melezitose. The phenomenonological parallel between ultra-violet sensitivity of the patterns on the chromosome and the activity of the cytoplasmic proteinaceous enzyme suggest the possibility that both the receptor and the enzyme are protein. If the receptor-protein on the chromosome and the enzyme-protein in the cytoplasm are similar, the synthesis of enzyme in the cytoplasm involves a replication of the structure of the receptor in the cytoplasm. But this process must involve many intermediary steps because the synthesis of enzyme occurs in the cytoplasm far from the locus of the gene, where the induction occurred, and the protein itself does not pass from the nucleus into the cytoplasm. The biological economy achieved by constructing both receptors and enzymes from amino-acids probably lies in the fact that a pool of twenty activated amino-acids can serve as a source of protein which can be folded into almost any conceivable shape.

Mechanism of Gene Action

Enzymes are supposed to split carbohydrates by possessing a surface which almost fits the carbohydrate. If a disaccharide such as turanose impinges upon the enzyme surface it is subjected to distortion because the 'fit' is not perfect. This leads eventually to splitting the disaccharide into its two hexose components. The present theory of protein synthesis proposes that proteins are synthesized in the cytoplasm by the alignment of a series of activated amino-acids on a ribonucleic acid template[18]. The ribonucleic acid template assembles the amino-acids into a protein which is the enzyme. The ribonucleic acid template is a crucial component of the transmittor of the gene-system.

I shall propose that the RNA template arises from the locus of the gene on the chromosome. On this hypothesis there are some exposed nucleotides of single-stranded DNA available at the locus which bind RNA and receptor-protein to the locus. Double helices of DNA may also be present to give the chromosome structural integrity, but it is single-stranded DNA which is associated with the RNA and the receptor. At each locus the structural DNA is held in its place in the linear continuum of the chromosome by a calcium bond at each end. The locus is also occupied by an RNA nucleotide, corresponding in length and in the distribution of similar or complementary nucleotides with those of the DNA chain. But the RNA chain is not bound into the long axis of the chromosome by calcium bonds. The DNA-RNA-protein-receptor complex becomes unstable when the inductor unites with the receptor-protein and the RNA-template is released from the complex. Because the RNA-template is not calcium-bonded it is free to leave the locus and travel to the nucleolus, where it is processed for its passage through the nuclear membrane and its action in the cytoplasm.

POSSIBLE ORIGIN OF MENDELIAN GENES FROM ENVIRONMENTALLY ACQUIRED CHARACTERS

Origin of Adaptive Enzyme-forming Systems

I have suggested that the genome 'stores' the capacity to produce adaptive enzymes. The preceding hypothesis concerning the mechanism of gene-action may form a basis for a hypothesis concerning the origin of gene-systems. On this hypothesis, eobionts, which resembled the cytoplasmic-like coacervates conceived by Oparin[19], grew on the accumulated organic material which had been produced by abiotic syntheses, using (at one time) simple monosaccharides as energy sources. As the available monosaccharides became exhausted, accumulation of non-utilizable substances, such as disaccharides, intruded into the eobiont. The presence of the disaccharides impinging on the proteins, being formed by the eobiont, led to the construction of imperfect mirror images of the disaccharides by the same processes which lead antigens to initiate the construction of antibodies in the presence of unfolded proteins[20]. The imperfect fit to the surface of the disaccharide might produce a state of stress in the disaccharide molecule, causing the molecule to split and making a new source of energy in the form of monosaccharides available to the eobiont. The released 'enzyme' could then repeat the process. The disturbance produced by the disaccharide would lead to a temporary modification of the eobiont. So long as the 'enzymes' persisted a 'lingering modification' like that suggested by Jollos[21] would persist. The enzymatic process might have a very low rate, but in the absence of other sources of energy the rate would not be important. For many millennia energy might have been provided from new sources by this adaptive mechanism. Eventually some of the protein may have folded simultaneously, both on a ribonucleic acid and a saccharide, and the RNA would form a template for synthesis and folding of more enzyme, thus giving the eobiont an advantage, especially because replication of the nucleic acid might take place according to the Watson–Crick[22] hypothesis. A mechanism for replication of the template would reduce the time of adaptation by a large factor. Perpetuation of the enzyme in the cytoplasm would be assured, and the survival value of the virus-like RNA-cytoplasmic-template would increase the chances of survival of the eobiont.

But the theory thus far does not mention a nuclear apparatus. I have proposed that the genome is a recent development[23,24]. Hence, it remains to suggest a mechanism by which the capacity of the cytoplast to produce enzyme might have become stored in the genome. If DNA were available in the eobiont, or in its vicinity, a pattern reflecting the pattern of the cytoplasmic RNA might be present in the DNA. (It is assumed that these events may have occurred long before the origin of nuclei or cells, when the eobiont was only a slimy plasm.) If the nucleotides in the DNA were so arranged that the RNA template of the enzyme could become attached to the DNA by hydrogen bonds, the enzyme, carried by the RNA to the DNA, would become the protein-receptor of the chromosomal gene. The DNA-continuum would provide a locus on which the RNA-enzyme complex could be held in place and on which the RNA-template could duplicate the 'receptor-enzyme'. If this triple complex were supplied with the necessary materials for its continued replication, and if it could be isolated from the rest of the plasm, a genome capable of bringing forth the production of enzyme in the cytoplasm on contact with appropriate substrates would be established in the eobiont and might be expected to be maintained even during periods when no substrate was available.

Relation of Acquired Characters to Genes

The purpose of this article is to suggest the possibility of relating environmentally acquired characters to Mendelian genes. A hypothesis is presented which suggests that capacities to produce enzymes, acquired by the cytoplasm, eventually may become Mendelian genes. Unless the first eobiont carried the total potential exhibited by the great variety of living things, both past and present, it seems reasonable *a priori* that acquired characters must have become genic characters. Since no other hypothesis relating environmental modifications (acquired characters) to genes has been proposed, this hypothesis must serve to fill a void in theoretical biology until it can be replaced by one more acceptable.

OBITUARIES

Prof. Maud Menten

Maud Menten, experimental pathologist, died on July 20, 1960, at the age of eighty-one in Leamington, Ontario. She was born in Lambton County, Canada, in 1879 and received the B.A. degree at the University of Toronto in 1904, the bachelor of medicine degree in 1907 and her M.D. in 1911. In 1916 she obtained a Ph.D. degree in biochemistry at the University of Chicago, where she studied with A. P. Mathews. Between 1904 and 1905 she was a demonstrator in physiology in the laboratories of A. B. Macallum. During 1907–8 she was a Research Fellow at the Rockefeller Institute for Medical Research, and, together with Simon Flexner and J. W. Jobling, was author of the first monograph of the Institute, a work on radiobromide and cancer. During 1910–12 and 1913–14 she was a Research Fellow at Western Reserve University in the sphere of Dr. George Crile. In 1913 she worked with L. Michaelis in Berlin, and this collaboration resulted in the famous paper on chemical kinetics which appeared in 1913 in the *Biochemische Zeitschrift*. In 1915–16 she did research in cancer at the Barnard Skin and Cancer Hospital in St. Louis, Missouri. In 1916 she joined the School of Medicine of the University of Pittsburgh, Pennsylvania, where she remained until her retirement in 1950. In Pittsburgh she was pathologist to the Children's Hospital of Pittsburgh from 1926 until 1950, and was a full-time teacher in the Department of Pathology of the Medical School; she rose to become a full professor of pathology. On retirement, she continued to do research work on cancer at the Medical Research Institute of British Columbia, until ill-health forced complete cessation of scientific activity in 1955.

Maud Menten was an avid research worker all her life. In Pittsburgh, despite full schedules as a hospital pathologist and teacher of pathology, she continued to make noteworthy contributions to scientific literature.

She was a versatile scientist, as becomes a pathologist. She will be best remembered at present for four pieces of work. Her work on enzyme kinetics with Michaelis in 1913 resulted in the Michaelis–Menten constant. In 1924, together with Helen Manning, she discovered the hyperglycæmic effects of salmonella toxins. In 1944, together with Andersch and Wilson, she determined the sedimentation constants and electrophoretic mobilities of adult and fœtal carboxylhæmoglobin; this has been stated to be the first use of electrophoretic mobility to determine differences in human hæmoglobin, antedating Linus Pauling. In 1944, together with Junge and Green, she developed an azo-dye coupling reaction for the demonstration of alkaline phosphatase in the kidney. This piece of work was called enthusiastically "a stroke of genius" by A. G. Pearse in the first edition of his book on *Histochemistry* because it opened up a field of enzyme histochemistry. Other research papers encompassed work on potassium in cells (with A. B. Macallum), radiobromide and cancer (with Simon Flexner and J. W. Jobling), oxidases, vitamin C (with C. G. King and O. Bessey), streptococcal toxins, histochemistry of glycogen, and nucleic acids in bone marrow. Other papers were published in the fields of physiology, chemotherapy, hæmatology and pathology.

Dr. Menten was a member of numerous scientific societies. Aside from science, she was a student of languages, music and art. She was a fine painter, and several of her canvases were hung in art exhibitions.

Maud Menten was untiring in her efforts on behalf of sick children. She was an inspiring teacher who stimulated medical students, resident physicians and research associates to their best efforts. She will long be remembered by her associates for her keen mind, for a certain dignity of manner, for unobtrusive modesty, for her wit, and above all for her enthusiasm for research.

Aaron H. Stock
Anna-Mary Carpenter

Prof. G. Bonnier

Prof. Gert Bonnier died on January 11 in Stockholm, where he had held the chair of genetics from 1936 until 1958. Even after his retirement he continued his experimental work until a few days before his death. He belonged to the generation of geneticists who, under the influence of the Morgan school, started to analyse the mechanism of heredity by means of experiments with *Drosophila*. One of his earliest papers, published before he had obtained his doctorate, is a thorough and ingenious study of secondary non-disjunction, which may gain renewed importance now that non-disjunction in man has proved to be a source of profound pathological disturbances. Crossing-over in triploids and attached *X*-chromosomes, chromatid interference, gynandromorphism and mosaicism were among the problems that interested him most. In 1947, together with B. and M. Rasmuson, he published a paper on "Gene Divisibility", which at the time of its appearance was somewhat of an oddity, but which now fits beautifully into the modern concept of the structure of the gene. After the War, Bonnier became increasingly interested in the genetical effects of X-rays and published a series of papers on this subject, several of them in collaboration with K. G. Luning, his successor to the chair. Perhaps the most interesting result of these studies was the finding that X-rays produce more mutations in spermatozoa when they are exposed in the inseminated female than when the male is treated. During the past few years, Bonnier's interest in radiation genetics shifted from these more fundamental aspects to the problem of radiation damage to populations, and he studied the genetical effects of X-rays in model *Drosophila* populations of different breeding structures and under different selection pressures. All these investigations are characterized by carefully thought-out and often novel techniques, by large and painstakingly collected data, by thorough statistical analyses and by cautious and critical interpretations.

To geneticists in general, Bonnier is probably best known as a pioneer in applied genetics. In 1928, he became the first chief of the Animal Breeding Institute in Wiad; he held this position until the Wallenberg Fund in 1950 withdrew its financial support. There he introduced the use of cattle twins for systematic studies of the effects of environment and nutrition on identical genotypes; similar groups of twins have now been collected and are being studied at many research stations throughout the world. He was also one of the pioneers of the use of artificial insemination in cattle, and the centre organized at Wiad in 1936 was the first of its kind in Scandinavia.

As a person, Bonnier was modest and shy, full of kindness and tolerance, and with a quiet sense of humour; he was respected by all who came in contact with him and loved by many friends and pupils. His father had owned one of the largest publishing houses in Sweden, and the tradition of culture and gracious living in which he had grown up was continued in the life of his own family. To have been a visitor in his beautiful house and to have enjoyed the warm hospitality of him and his wife is an unforgettable memory. His death will be deplored not only as a loss to genetics; it will also be a deeply felt personal loss for many people in many countries.

CHARLOTTE AUERBACH

NEW FELLOWS OF THE ROYAL SOCIETY

AT a meeting of the Royal Society on March 16, the following were elected to fellowship of the Society:

PROF. J. BADDILEY, professor of organic chemistry in the University of Durham, King's College, Newcastle upon Tyne, distinguished for his researches in organic and biochemistry, particularly in the field of coenzymes, nucleotides, and bacterial cell-wall constituents.

PROF. H. E. M. BARLOW, dean of the Faculty of Engineering, and Pender professor of electrical engineering and director of laboratories in the University of London, University College, distinguished for his work on engineering aspects of microwaves, particularly wave guides and semiconductors.

PROF. M. S. BARTLETT, professor of statistics in the University of London, University College, distinguished for his contributions to the methods of mathematical statistics and their application to physical and biological science.

PROF. R. E. BILLINGHAM, professor of zoology in the University of Pennsylvania, Philadelphia, distinguished for his studies on the pigmentary system of mammals and on tissue transplantation.

PROF. C. C. BUTLER, professor of physics in the University of London, Imperial College of Science and Technology, distinguished for his researches on the elementary unstable particles in cosmic rays.

DR. J. CHATT, head of the Inorganic Chemistry Department, Akers Research Laboratories, Imperial Chemical Industries, Ltd., Welwyn, Hertfordshire, and group manager of the Heavy Organic Chemicals Division, distinguished for his work on the chemical and physical constitution of co-ordinated metallic compounds.

PROF. B. H. FLOWERS, Langworthy professor of physics in the University of Manchester, distinguished for his numerous contributions to theoretical nuclear physics, especially the shell model of the atomic nucleus.

DR. L. H. GRAY, director of the British Empire Cancer Campaign Research Unit in Radiobiology, Mount Vernon Hospital and Radium Institute, Northwood, Middlesex, distinguished for his contributions to the effects of radiations on cells and to radiotherapy.

DR. S. H. HAUGHTON, inter-African scientific correspondent for geology, Commission for Technical Co-operation in Africa, Pretoria, formerly director of the Geological Survey of South Africa, distinguished for his many contributions to South African geology, especially in the fields of palæozoology, stratigraphy and economic geology.

PROF. RODNEY HILL, professor of applied mathematics in the University of Nottingham, distinguished for his contributions to the theory of continuous mediums, particularly to the plasticity of metals.

DR. H. E. HINTON, reader in entomology in the University of Bristol, distinguished for his work on insect biology, particularly on the larval stages of insects, and on classification and morphology of Coleoptera, Lepidoptera and Diptera.

DR. R. G. S. HUDSON, Research Fellow in the Department of Geology, Trinity College, Dublin, distinguished for his stratigraphical and palæontological researches in the Carboniferous of the North of England and in the Mesozoic rocks of the Middle East.

MR. C. F. KEARTON, managing director, Courtaulds, Ltd., Coventry, distinguished for his work on chemical engineering characteristics of volatile uranium products and for technological development in the textile industry.

Dr. H. London, deputy chief scientific officer at the Atomic Energy Research Establishment, Harwell, distinguished for his work on superconductivity, on liquid helium, and on the separation of isotopes.

Prof. M. Maizels, professor of clinical pathology in the University of London, University College Hospital Medical School, distinguished for his investigations into the mechanisms by which the electrolyte composition of animal cells is maintained.

Prof. Irene Manton, professor of botany in the University of Leeds, distinguished for her studies on the ultramicroscopic structure of plants and for studies on their evolution.

Dr. L. Marion, senior director, National Research Council of Canada, and director, Division of Pure Chemistry, Ottawa, distinguished for his work in organic chemistry, particularly in the field of alkaloids.

Prof. A. A. Miles, director of the Lister Institute of Preventive Medicine, London, and professor of experimental pathology in the University of London, distinguished for his contributions to bacteriology, and for his work on the mechanism of inflammatory reactions.

Prof. D. G. Northcott, Town Trust professor of pure mathematics in the University of Sheffield, distinguished for his work in abstract algebra and its application to algebraic geometry.

Dr. G. J. Popjak, director of the Medical Research Council Experimental Radiopathology Research Unit, Hammersmith Hospital, London, distinguished for his work on lipid metabolism and for elucidating the biosynthesis of fatty acids and cholesterol.

Dr. J. A. Pople, superintendent of the Basic Physics Division of the National Physical Laboratory, Teddington, Middlesex, distinguished for his work on the application of quantum mechanics to the explanation of the chemical and spectroscopic properties of molecules.

Dr. R. N. Robertson, executive of the Commonwealth Scientific and Industrial Research Organization, Melbourne, and professor designate of botany, University of Adelaide, distinguished for his contributions to plant physiology, particularly on salt accumulation and respiration and the ripening of fruits.

Dr. S. Siddiqui, director of the Pakistan Council of Scientific and Industrial Research, Karachi, distinguished for his work in the chemistry of natural products and for his leadership in the promotion of research in Pakistan.

Prof. A. W. Skempton, professor of civil engineering in the University of London, Imperial College of Science and Technology, distinguished for his pioneering work on soil mechanics, particularly in relation to the shear strength and other physical properties of clays.

Prof. M. J. D. White, professor of zoology in the University of Melbourne, distinguished for his contributions to animal cytology, particularly in relation to evolutionary processes.

NEWS and VIEWS

International Control of Investigations of Rare Meteorites

In recent years the study of meteorites has rapidly increased and, in the hands of investigators such as Urey, Anders, Wiik, Vinogradov and others, has thrown much light on the composition and origin of the solar system and of the planets. Last year, through the work of Mason on hydrous silicates in meteorites, interest has concentrated on the rarest form of meteorites, those which contain carbonaceous material. It follows from Mason's results, as well as from the earlier analyses of carbonaceous material by G. Mueller, that carbonaceous meteorites, unlike all other types, had never been subjected to high temperatures since their formation and that they might well contain samples of the raw materials from which life may have been formed on larger planets. On March 16, this hypothesis was given a new turn by the announcement at the meeting of the New York Academy of Sciences that Prof. B. Nagy, Dr. W. Meinschein and Dr. D. Hennessy had, by using mass spectroscopic and X-ray methods, found in the carbonaceous material from the meteorite which fell near Orgeuil in France on May 14, 1864, paraffinoid hydrocarbons characteristic of living organisms and hence had, in the opinions of these investigators, provided proof for the existence of life on its presumed parent body. This view is unlikely to go unchallenged, but whatever the final consensus of opinion, the crucial importance of this study of the carbonaceous meteorites is now evident.

The great publicity deservedly given to these observations and deductions has focused the attention of scientists in many countries on the carbonaceous meteorites. Paradoxically, the result may well be, unless appropriate steps are taken in time, to bring the researches to a rapid end by destroying the irreplaceable material on which they are based. There is known to be only some 30 kgm. of well-attested carbonaceous meteorites in museums. More, but not much more, may be in the hands of dealers or may be brought to light in other ways. Already these rare bodies are being examined in a dozen or more laboratories, each with a different objective and by methods which render the material useless for further study. This can only result in the exhaustion of the stock unless prompt measures are taken to ensure intranational and international co-operation similar to that in the various sections of the International Geophysical Year in the analysis of meteorites by different but complementary methods. The appropriate body for this is clearly the Committee on Space Research of the International Council of Scientific Unions, which, by a slight extension of its terms of reference, might cover bodies coming in from outer space as well as those going out into it. It is hoped that at the forthcoming meeting of the Committee at Florence, the matter can be discussed and appropriate measures taken in time to secure that the maximum of information is obtained from meteorites with the minimum of destruction.

Mathematics at Hull: Prof. G. C. Steward

THIS year Prof. G. C. Steward retires from the chair of mathematics in the University of Hull. He has occupied this chair since 1930, soon after the University College was first established. On his retirement, separate chairs of pure and applied mathematics are being instituted. Prof. Steward had his degree studies interrupted by the First World War, and he did not finally graduate at Cambridge until 1920. He was joint winner of a Smith's Prize in 1922. Meanwhile, he spent three years as assistant lecturer at Leeds before returning in 1923 to Cambridge as fellow and mathematical lecturer at Emmanuel College. He went directly from Cambridge to Hull. In 1918 he worked in the optics division of the National Physical Laboratory. This determined the course of his research work, which has been mainly on optical systems, using the eikonal function of Bruns, and other methods. He is the author of a Cambridge tract on symmetric optical instruments. In recent years he has been increasingly involved in departmental organization.

Prof. W. H. Cockcroft

DR. W. H. COCKCROFT, who is to be the first holder of the chair of pure mathematics in the University of Hull, was one of Prof. J. H. C. Whitehead's research students in the immediate post-war period. Since his doctorate at Oxford he has taught at the Universities of Aberdeen, Chicago and Southampton, where he is now a reader. His scientific interests are naturally directly derived from his early work under Whitehead. He was concerned in the first instance with various algebraic questions about group extensions and with some special problems arising in homotopy theory. He has since made contributions to homological algebra and topology generally. To mention one or two examples of research work of his, one may refer to some work which he and R. G. Swann have done in making improvements in the algebraic machinery used in Whitehead's work on simple homotopy types. In his work on the cohomology groups of a fibre space he has analysed the methods of the Belgian topologist Hirsch. In particular, he has obtained an explicit form for Hirsch's coboundary operator. This enables Cockcroft to make improvements in his own earlier work as well as to explain some results of Eilenberg–Maclane. Cockcroft has also taken great interest in the teaching of mathematics to undergraduates, and has taken part in symposia throughout the United States on the invitation of the National Science Foundation.

Prof. N. B. Slater

DR. N. B. SLATER, who has been appointed to the newly created chair of applied mathematics in the University of Hull, studied at the Universities of Edinburgh and Cambridge. For the year 1939–40 he was an observer at the Solar Physics Observatory, Cambridge; for the rest of the war years he was a member of Prof. L. Rosenhead's team in the Projectile Development Establishment. Since 1945 he has been on the applied mathematics staff of the University of Leeds, successively as lecturer, senior lecturer and reader. His Cambridge appointment led to a strong interest in amateur astronomy. It also led to an acquaintance with Sir Arthur Eddington, and, after the latter's death, Slater was asked to go through his unpublished manuscripts. He found that these cast a vivid light on the development of the ideas in Eddington's *Fundamental Theory*, and described what he found in a book published in 1957. However, Slater's main research interest has been in the theory of unimolecular gas reactions, on which he first began work under R. H. Fowler before 1939. In this field he has produced a standard theory, which has attracted a good deal of attention. A course given while visiting Cornell University was expanded by him into a book on the subject, which was published in 1959.

The National Reference Library for Science and Technology

IN an adjournment debate in the House of Commons on March 14, Mr. A. Albu asked a number of questions regarding the National Reference Library for Science and Technology. Stressing the value to the research worker of the open access system in the Patent Office Library, he questioned the adequacy of the proposed book stock of 500,000 current volumes, and thought that comparison with similar libraries elsewhere suggested a stock twenty times that proposed. He asked for specific assurances that the non-current volumes to be transferred to the British Museum would be readily available, that the site provided adequate room for expansion, and that measures were being taken to recruit staff of appropriate high scientific calibre. The Parliamentary Secretary for Science, Mr. D. Freeth, in his reply, said that it is not anticipated that there will be any overlapping or confusion of responsibility, although the Library will be part of the British Museum Library and come under the Chancellor of the Exchequer and not the Department of Scientific and Industrial Research and the Minister for Science. It will occupy a site to the east of the southern approach just north of the existing Cornwall Hall, and it is considered that the Library's total area of about 130,000 sq. ft. is well suited to house the 500,000 volumes required to provide the complete reference desired, together with an expert staff and open access. Reading rooms totalling about 22,000 sq. ft. will seat about 300 with seating room for a further 300 among the book stacks. The total cost is estimated at about £2·5 million.

Mr. Freeth said that the site does not provide room for all the expansion that might be desirable in future, but it is believed that it will provide a worthy national reference library, and that it will be possible to provide a speedy and adequate system for research workers to procure earlier publications from the British Museum. Legislation will be necessary for this purpose. The present stock of the Patent Office Library amounts to 210,000 volumes of periodicals, 100,000 volumes of patent specifications and 70,000 text-books; more than 7,500 current periodicals, including 300 Russian, are taken. Expenditure in 1960 was just under £180,000 and the staff numbered 72. Building plans have already reached an advanced stage, and Mr. Freeth said that any suggestions which prospective users might have for this building should be sent to the Principal Keeper in the Department of Printed Books in the British Museum, London, W.C.1, or to the Librarian, Patent Office Library, 25 Southampton Buildings, London, W.C.2. The exact constitution of the advisory committee to be set up when the new Library comes into operation is not yet decided. The Government is determined to see that the Library has an adequate expert staff ; there will be ample provision for photocopying, and the new Library will co-operate fully in research into information techniques.

Nestor: a New Reactor at Winfrith

A NEW 10-kW. reactor, *Nestor*, was put into operation for the first time at the Atomic Energy Establishment, Winfrith, on March 13. Its purpose is to act as a source of neutrons for sub-critical assemblies of nuclear fuels and moderators. The reactor core, control gear and instrumentation were designed and installed by the Hawker Siddeley Nuclear Power Co., which modified the design of its *Jason* reactor to enable up to five sub-critical assemblies to be driven simultaneously by the reactor. This concept represents a major advance in the use of a reactor as a neutron source. The Turriff Construction Corporation, Ltd., was responsible for the installation of the special shielding and the civil work generally. The nuclear fuel in *Nestor* is an alloy of highly enriched uranium and aluminium in the form of aluminium clad plates arranged in an annulus around a graphite cylinder, and natural water is used both as coolant and moderator. The reactor is provided with control and safety rods, and additional control is possible by varying the water-level. The experimental assemblies will be placed in 'caves' formed in the shielding at the sides and above the reactor. The whole shielding is arranged to be demountable so that the caves can be rebuilt to accommodate major changes in the requirements of the experimental programme.

The reactor is capable of operation at 10 kW. (heat), giving a thermal neutron flux of 10^{11} neutrons/cm.^{2}/sec. in the centre of the core and of up to 10^8 neutrons/cm.^{2}/sec. in the sub-assemblies. The thermal neutron flux for each sub-critical assembly can be varied by altering the reactor power-level, by using neutron shutters or by rearranging the fuel loading in the annular core.

Netherlands Atom Forum

A NUMBER of Netherlands industries together with the Reactor Centre of the Netherlands have taken the initiative for the establishment of the 'Netherlands Atom Forum'. The object of the new body is to give publicity to the developments in the field of nuclear energy, in particular to the activities in this domain, of the Netherlands industry and of institutes engaged in the subject. The intention is to do this by means of publications, the organization of conferences and information meetings, and the co-ordination of Netherlands participation in exhibitions. The Forum will also attend to the documentation and information on the development and application of nuclear energy, if possible in co-operation with existing organizations at home and abroad. It will in future represent the Netherlands in the 'Forum Atomique Européenne', which was established in Paris on July 12, 1960, and in which corresponding organizations from other Euratom countries, as well as from non-Euratom countries, have been brought together. Mr. W. A. de Haas, secretary of the Industrial Commission of the Reactor Centrum Nederland, has been elected chairman of the Netherlands Atom Forum ; the secretariat is accommodated at Reactor Centrum Nederland, Scheveningseweg 112, Den Haag.

Sea-water Purification Unit based on New Principles

A NEW type of evaporator developed for sea-water by the General Electric Co. of America may have application to other forms of heat exchangers, particularly because of the greater heat transference it achieves per unit area. The basis of its present form is a conventional steam-jacketed vertical copper tube 50 in. long and 6 in. diameter, from which evaporated vapour leaves at the top and concentrated brine at the bottom. The novel feature is the addition of wiper blades on a hollow shaft which sweep the inner surface of the tube at a speed of 300 ft./min. and spread sea-water issuing from the shaft and a header as a film some 0·001 in. thick on the wall. The tube is 0·05 in. thick and fluted lengthwise externally to provide increased heat exchange surface and improved removal of condensate; together with the wiper action heat transfer-rates of 40,000 B.TH.U./sq. ft./hr. can be obtained without perceptible carry-over of spray. It is claimed that with a throughput evaporation of 40 per cent a purity of one part of salt per million is achieved. The makers expect to realize a saving in weight and space of some 40 and 60 per cent, respectively, over conventional plants and have in mind systems evaporating 1,000–1,000,000 gallons daily.

Arts Graduates and Imperial Chemical Industries, Ltd.

A NOVEL method of directing attention to the opportunities existing at Imperial Chemical Industries, Ltd., for arts graduates is set out in an attractive handbook (*A Degree nearer Industry.* Pp. 40. By Kenneth Harris (London : Recruitment Section, Imperial Chemical Industries, Ltd.), 1960). Kenneth Harris, a well-known industrial journalist, was invited to carry out a survey of his own devising to find out what had happened to arts graduates in the different companies of the Imperial Chemical Industries, Ltd., during recent years. The report prepared by Harris is frank and not always complimentary to Imperial Chemical Industries, Ltd., but clearly shows that here is a company where young men of the right qualities are needed and can find their way to the top. The booklet could well be read by all arts graduates contemplating a career in industry—the picture painted by Harris is not dissimilar from that of many other large industrial organizations.

Durban Museum and Art Gallery

THE report of the Durban Museum and Art Gallery for the municipal year 1959–60 records the development of the new Marine Gallery on modern museum lines, and pleads once again for new buildings for both the Museum and Art Gallery (Pp. 20. Durban : Durban Museum and Art Gallery, 1960). A large and varied selection of temporary exhibitions were staged during the year and the collections at the Old House have been expanded and their display considerably improved.

British Technology Index

IF sufficient support is forthcoming, a new endeavour is to be made to index the contents of British technical periodicals. There have been at least two earlier attempts to do this, and it is probable that part of the reason for their failures was the absence of a cumulative index or volume. The new *Index* will have 11 monthly parts (no August issue) and a bound annual cumulation. It will be sponsored by the Library Association and will index about 400 journals, many of which are not already abstracted or indexed. It will produce each issue within six weeks of the publication of the journals concerned. The price will be about 15 guineas. Further particulars, and a prospectus containing a specimen page, are obtainable from the Association at Chaucer House, Malet Place, London, W.C.1.

Field Studies Council

That the Field Studies Council is performing a real service to learning is again clearly brought out in its annual report for the year 1959–60 (Pp. 32+4 plates. (London: Field Studies Council, 9 Devereux Court, W.C.2.) 1961). Between 1951 and 1960 the number of visitors to the centres has more than doubled and, in 1960, was well over 8,000. It is interesting that more than half the visitors went to study 'biological subjects', and more than 3,000 studied 'geographical and geological subjects'; only 315 students were concerned with the 'countryside and natural history subjects'. The figures reflect mounting pressure from grammar schools and training colleges, while the report indicates that the centres could have been filled many times over between March and Whitsuntide. During the year amenities at Slapton Ley were improved and the new geography block was completed at Dale Fort.

The World Meteorological Organization: 1961 Events

The World Meteorological Organization has announced its schedule of conferences and symposia to be organized during the rest of 1961: April 12–26, Commission for Hydrological Meteorology—first session (Washington); June–July, Regional Association III—South America—third session (Rio de Janeiro); August 6–12, international symposium on "Atmospheric Ozone and General Circulation", to be held in conjunction with the International Ozone Commission (Arosa); August 14–19, symposium on "Radiation", to be held in conjunction with the Radiation Commission of the International Association of Meteorology and Atmospheric Physics (Vienna); September 18–October 2, Commission for Aerology—third session (Rome); October 2–7, symposium on "Climatic Changes", to be held in conjunction with Unesco (Rome). Further information can be obtained from the Secretariat, World Meteorological Organization, Geneva.

The Night Sky in April

Full moon occurs on April 1d. 05h. 48m. U.T., new moon on April 15d. 05h. 38m. and full moon on April 30d. 18h. 41m. The following conjunctions with the Moon take place: April 9d. 06h., Saturn 3° S.; April 9d. 14h., Jupiter 3° S.; April 18d. 13h., Aldebaran 0·4° S.; April 22d. 05h., Mars 5° N.; April 25d. 05h., Regulus 1° N. In addition to these conjunctions with the Moon, Mercury is in conjunction with Venus on April 18d. 01h., Mercury being 9° S., and Mars with Pollux on April 23d. 03h., Mars being 5° S. Mercury is too close to the Sun for easy observation. Venus will be visible for a few days at the beginning of the month as a bright star low in the west after sunset, but later in the month it is too close to the Sun for observation. Mars sets at 2h. 50m., 2h. 20m. and 1h. 40m. on April 1, 15 and 30, respectively. Mars is an evening star, but conditions for observation are becoming less favourable. Its stellar magnitude on April 15 is + 1·1; its distance is rapidly increasing and its apparent diameter decreasing. Jupiter and Saturn are morning stars, both rising just over two hours before the Sun; conditions for observation are not favourable. There is one occultation of a star brighter than magnitude 6 during the month, observations being made at Greenwich: Aldebaran, disappearance April 18d. 12h. 24·3m., reappearance April 18d. 13h. 01·4m. The Lyrid meteors are active during April 20–22, the maximum being on April 22. The radiant is at R.A. 18h. 04m., Dec. + 33°, and conditions for observation are very favourable.

Announcements

Prof. Dragoslav Popovic has been appointed director of the International Atomic Energy Agency's Safeguards Division, in succession to Mr. R. M. Smith (Canada). Prof. Popovic is at present at the Boris Kidric Institute of Nuclear Science at Vinca, near Belgrade, and has been professor of nuclear reactor engineering at the University of Belgrade since 1958.

Dr. Karl F. Meyer, director emeritus and professor emeritus of the University of California's George Williams Hooper Foundation for Medical Research, has been awarded the Jessie Stevenson Kovalenko Medal of the U.S. National Academy of Sciences. The award has been made in recognition of Dr. Meyer's achievements as an investigator, teacher and administrator in medicine for more than half a century, and especially for his work on the role of animals as hosts for vectors of human disease.

The Worcester Foundation for Experimental Biology, Shrewsbury, Mass., with the aid of a grant from the Population Council, is continuing its post-doctoral programme for scientific training in reproductive physiology. Fellowships will be awarded to candidates possessing the Ph.D. or M.D. degrees, or their equivalents; they will carry a stipend of 5,500 dollars per annum and will be for a twelve-month period. Application forms can be obtained from Dr. Celso-Ramon Garcia, at the Worcester Foundation, and should be returned not later than June 1.

The British Hydromechanics Research Association is organizing an international meeting on "Fluid Sealing" at Grosvenor Hall, Ashford, Kent, during April 17–19. Further information can be obtained from Mr. H. Stephens, information officer, British Hydromechanics Research Association, South Road, Temple Fields, Harlow, Essex.

A symposium on "The Water Relations of Plants" is being organized by the British Ecological Society, and will be held at the Imperial College of Science and Technology, London, during April 5–8. Further information can be obtained from Dr. F. H. Whitehead, Botany Department, Imperial College of Science and Technology, Prince Consort Road, London, S.W.7.

The ninth annual general meeting and conference of the British Agricultural History Society is to be held at Seale Hayne Agricultural College, Newton Abbot, Devon, from the evening of April 5 until lunch-time April 7. Further information can be obtained from Mr. S. T. Morris, 1 Courtenay Park, Newton Abbot, Devon.

HISTORY AND PHILOSOPHY OF SCIENCE IN THE COMMONWEALTH

By Dr. W. MAYS

Department of Philosophy, University of Manchester

The General Problem

THE history and philosophy of science is a subject of increasing importance, both in the universities and outside them. In the universities, where the division between the sciences and the humanities is growing more acute, it has a most valuable part to play. By integrating diverse fields of study, it can do a great deal to ameliorate the evils of over-specialization.

Because of this it seemed worth while finding out how the subject was developing in the British Commonwealth universities, both in its teaching and research aspects. These universities form a fairly coherent unit, since, in most cases, they have been founded on the model of the British universities. To obtain this information, a questionnaire was sent out to a hundred universities, most of which were in Australia, Canada, India and South Africa. Out of these, thirty-nine reported activity in the history and philosophy of science, and to this information was added returns from twenty-one British universities[1].

Six groups of questions were asked: (1) was the university teaching the history and philosophy of science as a regular and independent part of the curriculum; (2) whether there was an established post or the expectation of one; (3) the type of course given; (4) the manner of treatment; (5) the value of the subject; (6) general remarks.

Value and Future of the Subject

Most of the replies stressed the value of the subject in university curricula. In the case of science students such courses were seen as a means of integrating knowledge of the physical world with the humanities and as a counter to specialization. So far as arts students were concerned, it was thought that courses of this sort enabled them to obtain a general scientific outlook, and made them conversant with the influence of science on philosophy and culture.

In most Commonwealth universities very few independent teaching appointments have as yet been made. Most of the lecturing appears to be of a stop-gap variety carried out by members of science, philosophy or education departments. What clearly emerged was that the most effective way of teaching the subject was through an autonomous department. In a modern university unless a subject has departmental independence and representation on the governing academic body, its chances of internal growth may be slight. Melbourne, the only Commonwealth university outside Britain to have an autonomous department, was firmly convinced of the benefits accruing from its independent position. It is also clear that in view of its importance, both as a subject in its own right and as an integrating discipline, there is a very strong case for the establishment of chairs in the history and philosophy of science, at least in the larger universities.

The following points were also made. More university teachers in the subject were needed: (a) for research, and (b) for undergraduate teaching. There was a need to include the history and philosophy of science as part of the general education of sixth-form pupils as well as undergraduates. As the demand for the subject in schools will probably expand, it would be useful to have courses in education departments for prospective teachers of the subject. Further, there would seem to be important teaching possibilities in the field of extra-mural studies.

Results of the Survey

In Great Britain the Universities of London, Oxford and Cambridge have well-established teaching and research departments. The oldest department is that of the History and Philosophy of Science at University College, London, founded nearly thirty years ago. It is, however, mainly concerned with postgraduate studies. Another London department is that of Philosophy, Logic, and Scientific Method at the London School of Economics, where both undergraduate and graduate courses are given. The Oxford and Cambridge Departments are more recent and are post-Second World War creations. At Cambridge, the history and philosophy of science may be taken as an optional half-subject in the Natural Sciences Tripos, and a certificate in the subject is also awarded. Oxford provides an extensive range of courses and awards a diploma. Research degrees may be taken at London, Oxford and Cambridge.

Aberdeen has a reader in the history and philosophy of science. In some modern universities a number of lectureships as well as extra-mural posts have been established. At others the subject is taught by scientists, philosophers or education department staffs. In Great Britain there is, as yet, no established honours school in the history and philosophy of science; but, in view of the value of the subject, it seems desirable that such a school be set up in the near future in one or more of the British universities.

The Australian universities are well ahead in the history and philosophy of science. Some of them are large in size, and they may have felt the need to introduce the subject in an attempt to solve problems relating to the integration of university studies. The Melbourne Department has a staff of six and two part-time tutors, and awards both honours and research degrees, as well as providing courses for other departments. Queensland and Sydney both have an established lectureship in the history of science. The Australian National University, Canberra, is contemplating making an appointment in this field.

Even among the smaller Canadian universities there seems to be an interest in the subject. In some of the university medical schools a course in the history of medicine is offered. At McGill University there is an established chair in the history of medicine, and Assumption University, Windsor, Ontario, has a professor of physics and the philosophy of science. There do not, however, seem to be any postgraduate or graduate degrees or diplomas available for interested students.

The overall picture in South Africa, at the moment, is that there are neither independent departments nor teaching posts. A fair amount of teaching is done by members of science departments, and there are a number of compulsory courses given at different universities. One University, Witwatersrand, apart from providing courses in the history and philosophy of science for B.Sc. students, has recommended the establishment of a teaching post.

Indian and Pakistani universities use the subject mainly for giving science students a historical background, and for broadening the interests of arts students. It is taught by lecturers in science and philosophy. Finally, there is a group of widely scattered universities and colleges—West Indies, Ibadan, Rhodesia and Nyasaland, and Hong-Kong—at which some instruction in the subject may be obtained. Out of these Hong-Kong seems to be the only one contemplating a separate course in the history of science.

[1] Mays, W., *Brit. J. Phil. Sci.* (November 1960).

THE CARNEGIE INSTITUTION OF WASHINGTON

ANNUAL REPORT

YEAR Book No. 59 of the Carnegie Institution of Washington* covers the year ended June 30, 1960, and includes the report of the president, Dr. Caryl Haskins (see *Nature*, March 4, p. 695), reports of Departments and Special Studies, as well as the administrative reports of the Executive Committee and the Auditors, and list of publications during the year. In his review of the year, Dr. Haskins again emphasizes the extent to which the growing-points of science arise at the line of contact between disciplines or depend on theoretical studies for guidance, so that fundamental and applied science really form a continuum. Growing-points have been particularly noticeable during the year in geophysics, the observation of outer space and of the stellar universe and in the study of the cellular structure of life and of its nature at the molecular level, and in all these fields the research workers of the Institution have contributed towards the understanding of our beautifully intricate and orderly world.

At the Mount Wilson and Palomar Observatories a cluster of galaxies, which are apparently receding from the Earth at about 138,000 km. per sec., was photographed with the 200-in. Hale telescope, and the cluster proved to be a strong source of radiation, particularly at the longer wave-lengths. It is estimated that the cluster is eight times as distant as the colliding galaxies in Cygnus *A*, and it is certainly several thousands of millions light-years distant from the Earth. Continued exploration of the interior of the Earth by the Geophysical Laboratory yielded results suggesting that the sharp transition in rock composition at some 400 km. below the Earth's surface may be at least partly due to a transition from one mineral form to another occurring naturally under the conditions of temperature and pressure at that depth. At high temperatures and pressures of 60,000–80,000 atmospheres, the iron–olivine fayalite has been metamorphosed into a dense spinel form, and since the olivines are very generally distributed within the Earth's crust and mantle, a transition from natural olivine to spinel may be a significant change associated with the structural discontinuity observed seismically at 400 km. Another feature of the year's work in this field was the synthesis of diamonds, while the opportunities implicit in the existence of the five independent nuclear age-dating methods continued to be explored, and new information was obtained which may help to resolve problems arising from the lack of agreement of ages obtained from zircon with those obtained from micas. A significant advance in the study of metastable phases and their relation to polymorphic transformations in sulphide minerals is noted, and an attempt to understand the structural mechanism of high-order transitions led to the conclusion that a mixed crystal is not a homogeneous edifice.

In the Department of Terrestrial Magnetism, a new 60-ft. radio telescope was installed which will be used to measure hydrogen clouds in our own Galaxy, and duplicates of the Department's extended antenna arrays for studying the radio emission of the Sun have been provided for collaborators in Chile, the Argentine and Uruguay, and, with assistance from the National Science Foundation, a duplicate of the Department's equatorially mounted parabolic antenna is to be built in South America, probably near Buenos Aires. Stress is laid on the Department's participation in the International Geophysical Year and afterwards in the International Geophysical Co-operation; but a major part of the scientific effort of this Department continues to be devoted to biophysics, particularly the study of protein synthesis by bacteria and other simple forms of life. During the year, ribonucleic acid was extracted from ribosomes in a manner that preserves hydrogen and magnesium bonds, and a unit equivalent to ribonucleic acid in a large ribosomal particle was obtained which could be broken down into units one-twentieth to one-fortieth of their size. These units were isolated from living cells and occur naturally both in the ribosomes and in the non-particulate fraction of the cells, and it also appears that the large ribosomal units are formed in the growing cell by assembly of these sub-units of ribonucleic acid and associated protein.

In the Department of Genetics, in work with the bacteriophage *T*2, which infects *Escherichia coli*, using chromatography on a column of basic protein, half molecules and quarter molecules of phage deoxyribonucleic acid have been identified, and the sedimentation coefficient and intrinsic viscosity of the quarter molecule point to a molecular weight of about 13 million. Evidence has also been obtained that formation of some proteins is at least linked with the development of phage deoxyribonucleic acid, and by comparing the effects of chloramphenicol when added at different times after the infection of bacteria with the *T*2 phage evidence was also obtained suggesting a correlation of the evolution of the resistance to radiation with the synthesis of deoxyribonucleic acid. Other work in the Department suggests that even mild chemical agents of cellular origin have mutagenic activity. The enzyme deoxyribonuclease proved mutagenic to *Drosophila melanogaster* under laboratory conditions, treatment of larvæ and imagines with deoxyribonuclease producing both recessive and dominant lethal effects and chromosomal re-arrangement in the flies.

* Carnegie Institution of Washington. Year Book No. 59: July 1, 1959–June 30, 1960. Pp. lvii+515+25 plates. (Washington, D.C.: Carnegie Institution of Washington, 1960.) Cloth bound, 1.50 dollars; Paper bound, 1 dollar.

In the Department of Embryology, use of the techniques of rapid serial radiography and cinéradiography provided direct evidence that arterial blood enters the maternal placenta from the endometrial arteries under a pressure sufficiently high to drive it through the intervillous space and towards the chorionic membrane of the fœtus. Injection of radiopaque dyes into the femoral arteries of anæsthetized pregnant rhesus monkeys and observation of the course of the dyes by rapid serial X-ray photographs or by cinéradiography yielded films showing with great clarity the predicted characteristic spurts of blood as the dye enters the intervillous space. A major programme was completed in which chicken spleen was used to study the properties of immunologically competent tissues and the course of cells emanating from spleen grafts labelled with tritiated thymidine was traced within embryonic chick hosts. The cells of both donor and host appear to contribute to the spleen reaction, the host cells predominating numerically.

A new technique used during the year in the Department of Plant Biology facilitated the detection of the several forms of chlorophyll, and experiments with the algal genus *Phormidium* showed that the pigment phycoerythrin increased efficiency of light absorbed by chlorophyll *a* 695 and other forms of chlorophyll *a*. It also appears that a maximum rate of *Chlorella* photosynthesis is reached only when the two photochemical reactions initiated by the two parts of interdependent pigments are proceeding in the correct ratio. Studies of the amino-acids isolated from cultures of *Chlorella pyrenoidosa* and examination of their carbon isotope composition indicated that some of the amino-acids, such as leucine and valine, contain markedly less carbon-13 than is present in the inorganic environment, and while others, like serine, had ratios much closer to the inorganic carbon dioxide used as input, the carboxyl carbons of all chains contained a higher proportion of carbon-13 than the remainder of the carbon chains of the amino-acid. If it can be assumed that the isotope abundance found in the lipids or in the non-carboxylic portion of aspartic or glutamic acids in *Chlorella* is characteristic of the fixation of carbon dioxide in carbohydrates, a considerable fraction of the carbon fixed in *Chlorella* must be incorporated by pathways other than those traditionally described for photosynthesis.

Further progress is reported in the development of image tubes for telescopes, and while further technical refinement is still required to remove imperfections, thirty-fold reductions in exposure time have been obtained as compared with direct photography. Dr. Haskins's review directs special attention to a report by Dr. F. Chayes, of the Geophysical Laboratory, "Correlation in Closed Tables", included in that Department's report, as an example of uncommitted research in the Institution. The research was stimulated by certain problems in petrography, but has novel and potentially useful conclusions applicable to the statistical analysis of data obtained in many branches of experimental science.

TECHNICIANS IN ENGINEERING AND CHEMICAL INDUSTRIES IN BRITAIN

THE results of a sample survey of the employment of technicians in the engineering and chemical industries, carried out in 1960 by the Ministry of Labour, are analysed in the *Ministry of Labour Gazette* of December.

Replies received from 309 of the 400 firms approached, of which three-quarters employed more than 1,000 workers and the remainder 100–999, indicated that in most groups the percentage of qualified scientists and engineers to the total number of employees is a little higher than the corresponding percentages obtained from the survey of scientific and engineering man-power made at the beginning of 1959. Technicians formed 8·7 per cent of all employees of the firms included in the survey, the figure varying from 11·6 per cent in the electrical engineering group to 4·1 in the 'other metal goods' group. Except in the chemical and allied industries, few women technicians were employed, the proportion for all groups being 4·6 per cent, and for the chemical and allied industries 10·4 per cent; in the latter group, 34 per cent of the women were employed in research and development laboratories and 54 per cent on testing, inspection and analysis.

In the chemical and allied industries the proportion of technicians to qualified scientists or engineers was 1·6 : 1, compared with 4 : 1 in electrical engineering and electronics, and 7·6 : 1 in motor-vehicles and aircraft. The average ratio for all groups was 4·2 : 1, but the inquiry confirms that for engineering industries as a whole 5 or 6 technicians are required for each technologist. In all but the chemical group of industries the shortage of technicians in January 1960, measured by the percentage of vacancies that occurred at the time to the total number of technicians employed, was rather less serious than the shortage of qualified scientists and engineers a year earlier. The forecast demand for technicians in the two years following the survey was in most groups about twice the number of vacancies occurring. Over the whole field, the largest number (32·7 per cent) of technicians was employed in the design and drawing office, and 29·1 per cent of all technicians were design assistants or draughtsmen, testing, inspection and analysis accounting for 14·4 per cent.

Design and drawing office work accounted for 40·7 per cent of all vacancies for technicians (67·5 per cent in shipbuilding and marine engineering firms), but in the chemical industry 44·6 per cent of vacancies were for laboratory technicians for research and development. An analysis of requirements for the next two years presented a similar picture. In the chemical group of industries 63 per cent of technicians had some qualification, and this group employed 43 per cent of all technicians with the General Certificate of Education at Advanced Level, while in the shipbuilding and marine engineering industry 58 per cent of technicians had a qualification. About 10 per cent of all the firms referred to apprenticeships, technician, student or drawing office combined with courses at technical colleges for which release on one day a week was granted, but nearly 70 per cent replied that no courses of instruction were provided.

HEALTH OF BRITISH SCHOOL CHILDREN

"THE great majority of school children are not only robust and healthy, but are taller and heavier than their predecessors", states Sir John Charles, the chief medical officer of the Ministry of Education, in his report for 1958 and 1959*.

Sir John says under-nutrition has almost disappeared in Britain, and the differences between the heights and weights of children in good and poor districts are lessening. More fat than under-nourished children are being reported, but the number in each group is small.

Only about five per cent of school children contracted a notifiable infectious disease in the years under review. Tuberculosis continued to decline. Poliomyelitis reached its lowest level for thirteen years, and vaccination against it was undertaken vigorously everywhere. There were local outbreaks of diphtheria that involved 47 school children in 1958, of whom five died; seventy-seven were affected in 1959 with no deaths. Advocating the continued need for immunization the report directs attention to the fact that "as recently as twenty years ago 55,000 persons contracted diphtheria annually, of whom almost 3,000 died".

The main cause of death among children is through accident. More children aged 5–15 years die from accidents than from all congenital malformations and of circulatory, genito-urinary infections and respiratory diseases altogether. In 1958, 869 children of 5–15 years died from accidents, including 395 from accidents involving motor vehicles, 174 from drowning, and 58 from burns and scalds; 113 fatal accidents took place in the home.

The second chief cause of death of children of this age-group is cancer. There were 499 deaths in 1958, mainly from leukæmia. Other causes were respiratory diseases, 253; congenital malformations, 185; infectious diseases, 137; genito-urinary diseases, 76; and only 53 from diseases of the heart and blood vessels. More children died from appendicitis (44) than from rheumatic fever and rheumatic heart disease (30); these conditions were once widespread and deadly. The report stresses the need for unremitting research into the causes of the so-called congenital diseases and defects. "Medical research gives us reason to believe that some diseases that we consider hereditary or congenital in origin may well be found to be due to adverse influences in pregnancy or infancy." These diseases and defects cause the death each year of about 4,000 children under the age of fifteen years and leave thousands disabled. To this must be added those who are mentally retarded or who are blind or deaf from birth or early infancy. Although most children are healthy and without blemish, there are tens of thousands who are disabled to a greater or lesser degree.

The report welcomes the increasing number of education authorities which are considering, or who have already started, a modification of the fifty-year old system of periodical medical examination. In these areas all children will be examined after first starting and before leaving school; but, instead of a periodical examination of intermediate age-groups, doctors will visit the schools more frequently and give more attention to the new children who appear to need it. The hope is expressed that school doctors will be able to give more time to the study of particular diseases and disabilities as they affect children at school. Illustrations given are respiratory diseases—as many as 100,000 boys and girls have asthma some time during their childhood—and the nature and effects of skin diseases, from which tens of thousands of children are still reported to be suffering.

In 1958 more than two million children were examined at periodical school medical examinations. More than 809,000 were examined in schools and clinics at the special request of the parents, doctors, nurses, teachers, or others, and nearly 1,044,000 were re-examined for defects found at a previous examination. The comparable figures for 1959 were 2,138,000; 704,000 and 1,041,000.

About 15 out of every 100 children who were examined after first starting school were found with some defects which required treatment; in some areas, from one in five to almost one in two of these were not receiving it. Often the parents did not know of the defect or did not appreciate its significance. Prevalence of defects found at periodical inspections shows that 175,000 are treated annually for skin diseases; 200,000 orthopædic defects, mostly slight; 15,000 boys and girls are under treatment for epilepsy; 2,000 boys and girls of school age have diabetes. There are fewer children with heart disease. Of every thousand boys and girls examined, twelve had a heart defect in 1958 compared with eighteen in 1948. The recorded prevalence of lung disease in school children has become almost stationary since 1948. Of every thousand children examined 24 were found with lung disease in 1948 and 25 in 1958.

Although the number of verminous children is still "deplorably high"—219,000 in 1958 and 223,000 in 1959—it is less than half the figure of 464,000 in 1948.

---

* The Health of the School Child: Report of the Chief Medical Officer of the Ministry of Education for the years 1958 and 1959. Pp. iii+231+8 plates. (London: H.M. Stationery Office, 1960.) 10s. 6d. net.

A small number of children attend school inadequately clad. There is, however, widespread comment about the unsuitable types of shoes worn by many children, especially older girls. A school doctor in Hertfordshire reported that younger children were well shod, but that "many girls of secondary school age would not be guided otherwise than by the dictates of fashion".

The report says that it is doubtful whether children will refrain from smoking so long as they see their parents and teachers enjoying the habit. A survey of about 3,500 boys and girls in two grammar schools and four modern secondary schools in a county borough near London shows that eight per cent of the children are 'regular' smokers—the smoking of five cigarettes a week being defined as regular for the purposes of the survey. One third of the children aged 14–16 who are 'regular' smokers smoke more than twenty cigarettes a week. Another survey carried out in Oxfordshire of about 8,300 children shows that nearly 1,600 are smokers and spend £4,350 a year on cigarettes. Nearly half these children say that they have heard that there is some connexion between cigarette smoking and lung cancer.

The report emphasizes that, generally, facilities are adequate for medical treatment, but are seriously inadequate for dental treatment; the national shortage of dentists is the main deficiency. The school dental service is able to treat only a little more than half the number of children who require treatment. A large number, many of whom attend non-maintained schools, are treated by the general dental service, but hundreds of thousands are neglected.

In 1959, for the first time, the number of part-time dentists did not balance the number of whole-time dentists who retired or who left the service.

Special surveys of the teeth of the 5–12 year old children in eight representative areas show that deterioration of the teeth was less in five-year olds, but greater in twelve-year old children between 1953 and 1958 than between 1948 and 1953. "It is significant that during the period 1948–1958 sugar consumption per head in the United Kingdom rose from 88·3 lbs. in 1948 to 103·1 lbs. in 1953 and 120·7 lbs. in 1958", states the report.

The report of the working party set up in 1949 "to direct and organize an investigation on the prophylactic effects of the local application of a solution of fluoride to school children's teeth", is published as an appendix to the report. The working party considers that the application of a fluoride solution to the teeth is not a worthwhile preventive measure in the conditions of the investigation, that is, when the treatment is given on a wide scale in the public dental service. This may well enhance the interest already being taken in alternative methods of caries prevention, such as fluoridation of drinking water and the dental health education of the public, and especially children, in such matters as proper diet and the cleansing of teeth.

A notable feature of the work of the School Health Service in the years under review is the increased attention given to children with emotional or behaviour problems, and also of those with speech defects, but there was a serious shortage of child guidance clinic staff and of speech therapists. Much attention was paid to handicapped children; 54 new special schools, with accommodation for 5,732 children, were opened in 1958 and 1959, bringing the total number of handicapped children in special schools to more than 60,000. Much interest, too, was taken in children with defective hearing, and an increasing number of local education authorities employed peripatetic teachers of the deaf to visit children in ordinary schools, or opened special classes in ordinary schools for partially hearing children. During this period a large number of the new Medresco transistor hearing aids were supplied to school children.

Sir John insists that a school health service cannot ignore the challenge of children from problem families, of those who have been before the courts, or of promiscuity among some older adolescents. These boys and girls formed a small minority of the school population, but they presented "a tough problem to the medical, education and social services—three services that must work together".

Appendixes to the report include, in addition to the usual statistical tables, a list of the research projects being undertaken in the school health service and an index to *The Health of the School Child* for the period 1935–57.

STRENGTH AND PROPERTIES OF TIMBER

RESEARCH into timbers is undertaken in England at the Forest Products Research Laboratory, Princes Risborough, and is under the auspices of the Department of Scientific and Industrial Research. *Forest Products Research Bulletin* No. 45, entitled "The Strength and Properties of Timber", by F. H. Armstrong*, supersedes two earlier ones on the same subject and contains fresh material. Information on the properties of no fewer than 172 kinds of timber is presented in the proportion of some 37 home-grown timbers to 136 imported timbers, figures which may appear to some to be rather disproportionate, but the Laboratory has done a useful service to Commonwealth countries while not actually ignoring home-grown material, which has been handled more intensively. The technique of timber-testing has made considerable advances in recent years, and one new development in England has been the adoption of the 'Monnin' system, which makes use of 2-cm. square instead of 2-in. square test-pieces, and is thus more suitable for small-diameter trees.

The gist of this *Bulletin* consists of three tabular statements occupying about 16 pages. The physical and mechanical properties of home-grown timbers are given in Table 1, those of imported timbers, based on 2-in. test-pieces, in Table 2, and those of imported timbers, based on 2-cm. test-pieces, in

---

* Pp. vi+34+8 plates. (London: H.M. Stationery Office, 1960.) 3s. 6d. net.

Table 3. The contents of species in the last two tables do not conform. The data refer to the eight tests made, namely, six tests of physical properties, of (*a*) static bending, (*b*) impact bending, (*c*) compression parallel to grain, (*d*) hardness, (*e*) shear parallel to grain, and (*f*) cleavage, supplemented by physical tests of moisture content and specific gravity. These tests and the apparatus used are described in some detail with the help of photographs. Since the most important factors which influence the strength of a timber are its moisture content and specific gravity, these are dealt with in some detail. Regarding the latter, it appears that, in respect of the actual wood substance, it is for all practical purposes the same for all species, but that the amount of that substance varies with the species, so that there is, in fact, a wide variation of specific gravity, and strength, not only between different species but also within each species. The strength values given in the tables are primarily intended for a comparison of species. Here it must be pointed out that while the pieces tested may be representative of variation of the properties within individual trees or small groups of trees, they can scarcely be said to be fully, or even fairly, representative of any species for the whole range of conditions under which it is grown. The largest number of trees or planks tested refer to Weymouth pine (56), Corsican pine (38), beech (36) and Scots pine (35), whereas for some tropical species a single tree has provided all the test-pieces.

In this connexion the presentation of the data can be criticized on the grounds that the first letter of a name is not a good scientific basis for grouping, although it is admittedly useful in locating a species within a group. It does seem incongruous, for example, to find horse chestnut sandwiched in Table 3 between dahoma and North Bornean kapur. The grouping adopted here might have been taken a little farther; there would have been no disadvantage if the timbers of each country had been grouped together—in alphabetical order.

An interesting and unexpected feature of the *Bulletin* is an introduction to simple statistical methods useful in comparing results or testing relationships between variables, and justifiably applied here in handling the data from many samples from one tree or group of trees from one source. The recognition of the possible importance of such factors as capacity to resist fungous attack or the effects of atmospheric fluctuations seems to indicate a new outlook. The value of the graphs presented in Fig. 5, showing the relationship between specific gravity and maximum compressive strength, is much impaired by the absence of a key to link up the plotted numbers with the corresponding species.

This publication is a useful contribution to our knowledge of the properties of a wide range of timbers, many with very odd names, and it should be of value to importers and to timber-growers in Commonwealth countries who are endeavouring to find markets for so-called 'secondary' timber trees. To the layman it should convey some idea of the widely varying character of timber as a raw material.

DUCTILE BERYLLIUM

SOME fifty years of work on the production of ductile beryllium would appear to have come to full fruition by the announcement by the Chesterfield Tube Co., Ltd., a subsidiary of Tube Investments, Ltd., of its ability to supply this metal in a variety of sections, including finned tubes, with mechanical properties in the hot-extruded state, which include a tensile strength of 30–45 tons per sq. in. and an elongation in the longitudinal direction of 4–10 per cent*.

The problem of overcoming the brittleness of beryllium has been approached by controlling the purity of the metal, by reducing the grain-size and by control of the crystalline orientation. Although the two first avenues can exert beneficial effects, it is the last that, at present, offers the most promising line of attack. As a result of its hexagonal structure, beryllium shows marked anisotropy both of strength and ductility. At ordinary temperatures the main slip occurs on the basal plane and on the prism faces in the <1120> direction; the critical stress needed to initiate basal slip being about one-fifth of that on the prism face. Very little basal slip can, however, take place before fracture occurs, while quite extensive slip can occur on the prism face provided that the orientation is such that slip on the basal plane is inhibited. As the temperature is raised, the stress necessary to produce prismatic slip falls, and at 500° C. it is the same for both forms.

Mechanical operations such as rolling or extrusion result in a preferred orientation of the crystals to which hexagonal metals are particularly prone, whence the behaviour of extensively worked material approaches that of a single crystal. As a result, a tensile force applied normally to the basal plane results in a brittle fracture, but a force parallel to that plane leads to considerable ductility. In an extruded flat section, for example, the basal planes tend to lie parallel to the sides of the flat, the longitudinal ductility of the section being high, 5–15 per cent elongation, but transversely, the ductility may be negligible. The extrusion techniques which have now been developed control the orientation of the grains, so that in a tube the basal planes, instead of radiating from the tube axis, are randomly orientated over the cross-section. Bursting tests at 600° C. have shown 10 per cent expansion at failure for such randomly orientated tubes as compared with 2–4 per cent for tubes with the radial texture.

It would appear that, although beryllium with some degree of ductility has been known for some time, this is an important step forward which, moreover, may well have applications to other hexagonal metals, for example, magnesium.

DEPOSITION OF FISSION PRODUCT NUCLIDES AFTER TWO SAHARA NUCLEAR TEST EXPLOSIONS

By Dr. V. HAVLOVIC

Institute of Medical Physics of the Charles' University Medical Faculty in Plzen, Czechoslovakia

THE daily concentration of the radioactive dust particles as short-lived radium and thorium daughter products and long-lived fission products from nuclear test explosions in ground-level air have been estimated by the filter sampling method over several years[1]. Continuous measurements of the radioactive fall-out and rain-out in weekly and monthly intervals were added to the previous methods later[2]. The influence of two Sahara nuclear test explosions (on February 13 and April 1, 1960) on the fission product nuclides in the ground-level air in Czechoslovakia was not characterized by a sudden rise of fission product activity, but by a slow increase during the second quarter of the year 1960. The beginning of this increase appeared at the end of February. This observation is in satisfactory agreement with the simultaneous measurements of the radioactivity in the fall-out and rain. The increase of the fission product nuclides in the ground-level air in the mean monthly values is evident: the mean fission product activity during the second quarter of the year 1960 was about 320 per cent higher than that during the fourth quarter of the year 1959 (= 100 per cent): the latter was the lowest during the whole year 1959 as a result of the stopping of nuclear test explosions on November 1, 1958.

During March 1–17, 1960, the fission product content of rain-water presented several high peaks as a result of the first French nuclear test explosion. After April 8, 1960, a new increase in the fission product nuclides in rain-water was observed as a consequence of the second Sahara nuclear test explosion. The radioactivity deposited on a 1-m.^{2} area was, for example, on March 1, 1960, 42 times greater than on February 27, 1960. The fission-product activity in the rain-water after the second nuclear weapon test showed no further peaks after the first one and its activity was much lower. The increase in the rain-water activity as a result of two Sahara nuclear tests lasted until June 1960. An interesting result is demonstrated by the mean monthly fission-product activities in the rain-water expressed as specific activities of 1 litre rain-water: if the mean activity in January 1960 is regarded as 100 per cent, February shows 98 per cent, March 795 per cent, April 244 per cent, May 170 per cent and June 77 per cent. The activities of the rain-water deposited monthly on a 1-m.^{2} area were remarkable too: if the mean activity in January 1960 is regarded as 100 per cent, February was 53 per cent, March 1,360 per cent, April 455 per cent, May 186 per cent and June 132 per cent.

Moreover, the deposition of radioactive dust which is removed from the atmosphere by wash-out in rain-water and by dry deposition directly on to surfaces was observed at weekly and monthly intervals by the pot-method. The weekly fall-out radioactivity results are presented in the histogram (Fig. 1). Two peaks may be seen there, the first one in the tenth week (February 29–March 6, 1960), the second one in the fifteenth week (April 4–10, 1960), as a result of the second nuclear test explosion.

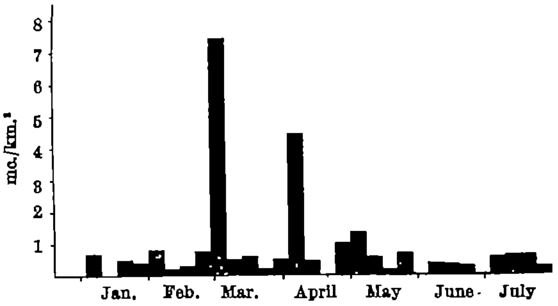

Fig. 1. Histogram of weekly deposited radioactive fall-out in the first half of the year 1960

Another method of autoradiographical research on the deposition of radioactive dust was tried in this laboratory independently of the macroscopical research methods described of observing fission-product nuclides in the ground-level air and in fall-out and in rain. This method rendered possible a microscopical observation of the deposited radioactive dust particles. For this purpose, glass plates (18 × 24 cm.) covered by a film of 'Vaseline' mixture were used. The sticky glass-plates were exposed for the deposition of the fall-out and rain in the free atmosphere for 14–21 days. Afterwards they were put for three days in a dust-free box for short-lived radium and thorium daughter products decay. Then the glass plates ready for autoradiography were covered with a thin plastic foil and pressed to a X-ray film (Agfa Laue film) for a longer period. The exposed X-ray film was developed in a hard-working developer.

The radioactive fall-out dust particles deposited, and fixed on the sticky surface, could be seen on the X-ray film after developing as dark centres of variable size and blackening. An interesting illustration of the quantity and quality of deposited radioactive fall-out dust particles on to the Earth's

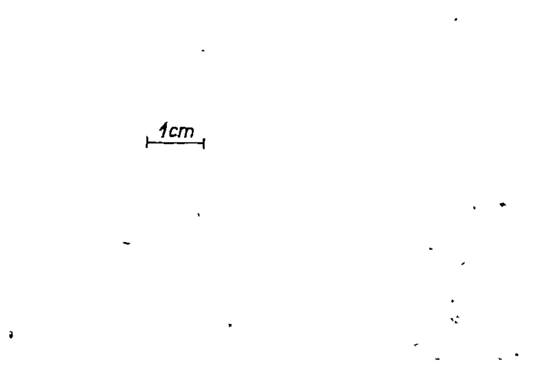

Fig. 2. Autoradiogram of radioactive dust particles deposited from the atmosphere from March 7 to March 20, 1960, on a sticky glass plate

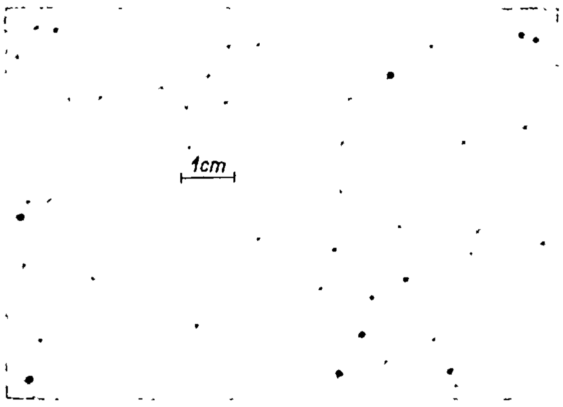

Fig. 3. Autoradiogram of radioactive dust particles deposited from the atmosphere from March 21 to April 10, 1960, on a sticky glass plate. It contains several 'hot' particles in consequence of the second Sahara nuclear test explosion

surface was given by the number and the blackening of centres.

Several glass plates exposed during the beginning of the year 1960, including that exposed in the ninth and tenth weeks (February 22–March 6, 1960), when a great peak in the weekly fall-out results was observed (Fig. 1), were not successful owing to a short autoradiographic exposure. The next glass plate exposed in the eleventh and twelfth weeks (March 7–20, 1960) gave an autoradiogram presented in Fig. 2. It contains only four radioactive centres of varying size and blackening. This result is in general agreement with the fall-out histogram in Fig. 1. The next glass plate exposed in the thirteenth to fifteenth weeks (March 21–April 10, 1960) is presented by its autoradiogram in Fig. 3. It gave a very clear result: it contains much deposited radioactive fall-out dust particles of different size and blackening. This autoradiogram demonstrates the presence and the deposition of a great mass of radioactive dust particles from the atmosphere, probably as a result of the second Sahara nuclear test explosion. This information is in good agreement with the second peak on the histogram in Fig. 1.

The further autoradiograms of glass plates, exposed in the free atmosphere in November 1960, contained several radioactive centres of small activities only. Thus the results described were verified, and an argument presented for a new purification of the atmosphere from the fission product nuclides in agreement with the results reached by other methods.

The deposited radioactive dust particles from the atmosphere create 'hot' particles with greater activity of the order 10^{-9} c. by agglomeration processes from smaller ones; several large centres in Fig. 3 may be due to 'hot' particles.

The concentration of fission product nuclides on dust particles has raised many new physical, biological and hygienic problems. As there is a possibility of inhalation of 'hot' particles or incorporation in some other way a radiobiological danger of irradiation arises, for example, on the endothelium of the bronchi.

A RADAR OBSERVATION OF A SEA-BREEZE FRONT

By Dr. E. EASTWOOD and G. C. RIDER

Baddow Research Laboratories, Marconi's Wireless Telegraph Co., Ltd.

IN the course of an investigation of the origin of radar 'angels', an unusual line source of radar echoes was recorded. Photographic time-compression techniques enabled the development and progress of the line echo to be investigated in detail. The photographic techniques and the parameters of the 23-cm. radar installation used have been previously described[1-3].

Fig. 1 shows the line echo as it appeared on the radar plan position indicator at 1700 hr. (6 p.m. B.S.T.) at about its maximum intensity, the isochrones on Fig. 2 indicating its development and movement. The line first became evident at about 1200 hr. along the coast near Felixstowe; it then moved inland, increasing in intensity and accelerating gradually until sunset, by which time it had reached nearly 50 miles inland and was moving at 6 knots. A similar line developed over Kent and Sussex, moving inland in a similar way. The whole phenomenon decayed rapidly over the sunset period 1930–2000 hr.

Scintillating discrete angels could be seen breaking away from the line during its strongest period; on the eastern side of the northern segment over Hertfordshire and Suffolk, and from both sides of the Sussex segments of the line.

In addition to the line echo the screen was well covered with discrete angels during this day. Most were of the short-lived, or rapidly scintillating kind, and these showed no very obvious pattern of movement. However, a well-marked stream of persistent angel echoes could be seen moving up the Thames estuary, and some of these could be tracked for considerable distances, occasionally even across the line echo.

The development of the line at the coast and the speed and form of its movement inland suggest a sea-breeze effect, and this appears to be confirmed by the meteorological evidence.

On June 20, 1960, an anticyclone covered the country, and there was almost no cloud and little wind. The data of Table 1, taken from the Daily Weather Report, indicate the changes over the afternoon at some relevant stations.

Table 1

Station	1200 hr. (G.M.T.)				1800 hr (G.M.T.)			
	Wind		Temp (°F.)		Wind		Temp.(°F)	
	Speed	Direction	Air	Dew pt.	Speed	Direction	Air	Dew pt.
Felixstowe	17 kt	50°	66	49	13 kt.	60°	62	51
Mildenhall	3 kt.	20°	60	52	5 kt.	40°	70	44
Gatwick	9 kt.	350°	71	51	6 kt.	90°	75	56
Thorney Island	4 kt	320°	73	45	2 kt.	200°	71	55

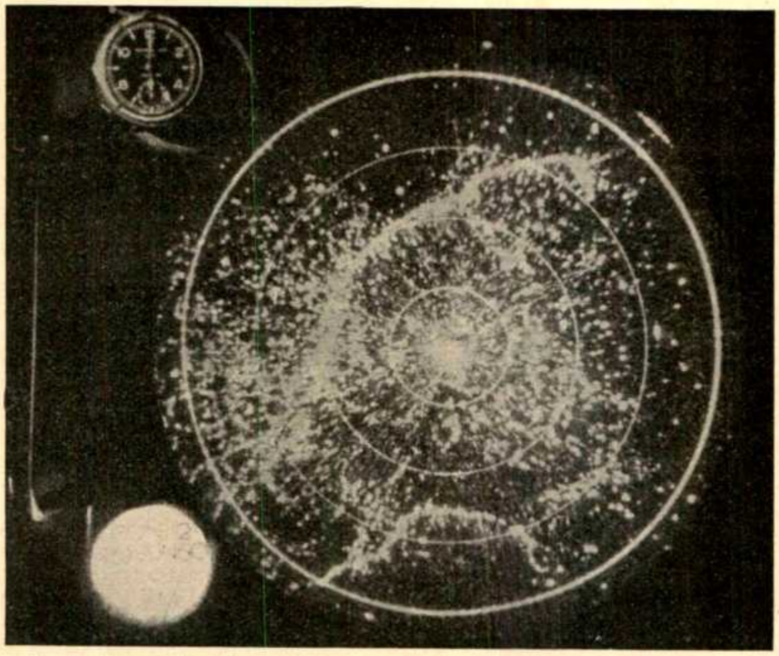

Fig. 1. Plan position indicator photograph, 1700 hr., June 20, 1960 (clock shows B.S.T.)

The line echo passed over Gatwick and would doubtless have been observed to pass over Thorney Island also if this station had been within range-setting of the radar display photographed. The changes in wind direction and in dew point at these two stations thus appear to offer good confirmation of the sea-breeze hypothesis.

It appears, then, that the radar was in fact seeing a remarkably well-developed sea-breeze front, for its maximum penetration inland was about 50 miles, while its greatest length, including both north and south segments, was little short of 120 miles.

It is of interest to consider the mechanism by which the radar energy has been reflected from the front. Cloud echo can be eliminated both by the plan position indicator appearance and by the 0/8 cloud reported by the relevant synoptic stations. The necessary echoing area must therefore be provided either by birds or by refractive index effects in the gaseous atmosphere. Formally, of course, both factors certainly contribute, and in this case it will be shown that each can make a significant contribution.

The discrete angel echoes moving away from the line echo have already been mentioned. They scintillate strongly, and move from the line at a velocity of about 30 knots, though the scintillation makes accurate measurement difficult. As discussed below, the frontal zone is a region of strong convection, so that soaring birds may well be present along the line echo, and may account for the angels breaking from it, since the velocities measured are of the correct order. A small flight of birds would provide sufficient echoing area to account for these angels, and if many such flights were air-borne, soaring in the frontal region, their resultant echo would present the continuous appearance seen, as in the case of the ring angels already shown to be due to starlings[2]. The sharp edge seen in the frontal echo is also evident in the rings.

We now consider the magnitude of the echoes to be expected from the refractive discontinuities.

Excepting the front under discussion, the synoptic situation was almost stationary throughout the day, and the radiosonde ascent from Hemsby at 1100 hr. gives adequately representative data. The atmosphere was very stable and abnormally dry to 1,400 m., and the refractive index profile shows a step discontinuity of 13 N units at this level ($N = (n - 1) \times 10^6$; n being the refractive index coefficient). The slope of the N profile is otherwise as for a standard atmosphere. The refractive index of the sea-breeze air may be estimated as follows. Air having the moisture content shown by Felixstowe at 1800 hr. (dew pt. 11° C.) and warmed to the temperature shown by Cardington (22° C.) is transported adiabatically to 1,400 m., at which height a difference of 30 N units is shown with the ambient air.

The frontal region is thus considered as a line of thermals rising to about 4,000 ft. In the absence of mixing the rising air differs from its surroundings by 30 N units at this level.

If this discontinuity can be considered sufficiently sharp, taking place, for example, in about 5 cm., then a plane reflexion coefficient:

$$\begin{aligned} \rho &= \tfrac{1}{2}\,\Delta n \\ &= 1{\cdot}5 \times 10^{-5} \text{ may be used (ref. 4, p. 7)} \end{aligned}$$

If the beam is filled with such a sheet, from 4,000 ft. to say 1,000 ft. at ground cut-off, the signal received may be calculated to be 1 db. below the threshold of detection.

The actual target configuration is not a plane sheet, however, but numerous discrete thermals, rising somewhat 'doughnut' shaped; for example, as described by Scorer[5]. Each thermal thus presents

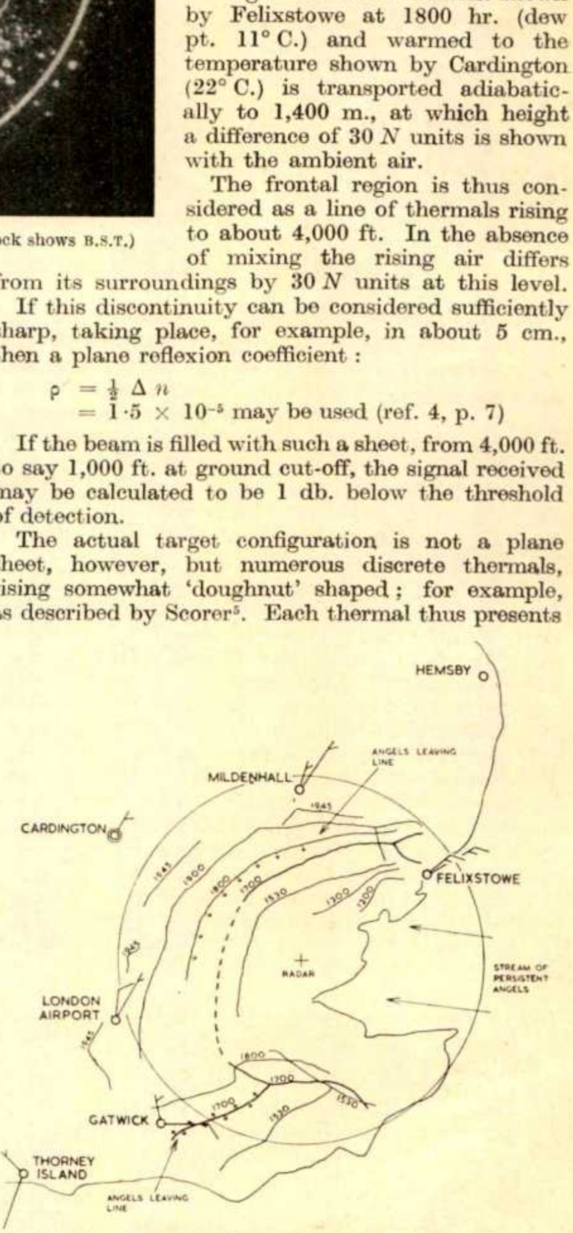

Fig. 2. Development of the sea-breeze front, June 20, 1960. Range ring 40 nautical miles. Surface winds: 1200 hr., short arrow; 1800 hr., long arrow

the discontinuity to the incident energy many times, and though the intensity of the reflecting boundary must decay due to mixing, there is also the possibility of focusing of energy from the rear surface of the thermal column. It appears quite possible that such thermals, probably filling the pulse volume in depth, may provide a returned signal greater in intensity than the hypothetical plane sheet used in calculation.

Rather similar line echoes have been reported by Atlas[6], and by Ligda and Bigler[7], each favouring a refractive explanation similar to that offered above. In the former case, using 1·25-cm. radar, the absence of birds was verified. However, Harper[8] has produced evidence in favour of soaring birds as the backscatterers responsible for some line echoes of somewhat similar appearance.

In conclusion, we comment on the length and penetration inland of the sea-breeze front observed, and secondarily note that in this case it seems probable that both birds and refractive discontinuities have contributed to mark its passage.

We thank our colleagues, especially in the Radar and Photographic Groups, who made the observations possible.

DIFFUSION THROUGH POROUS MATERIALS

By J. R. BELL and Dr. P. GROSBERG

Department of Textile Industries, University of Leeds

It is often necessary to calculate the amount of a gas or vapour diffusing through a porous bed of material. The diffusion is less than that through the air because of the interposing solid portions through which, in general, there is virtually no diffusion. Usually an attempt is made to relate the ratio D/D_0 to the porosity ε, where D is the diffusion coefficient for diffusion through the porous structure, and D_0 is the corresponding coefficient through air. For example, in the later stages of the drying of thick porous structures the water surface retreats inwards and the falling rate of drying is maintained by the diffusion of water vapour from the surface of evaporation through a layer of the dry material. In calculating this diffusion, Nissan, Kaye and Bell[1] made the simple assumption that, with no diffusion through the solid, the area available for diffusion would be the average area of the air space, that is, εA, where A is the total area of cross-section. This means that D/D_0 is equal to ε. This relationship was adequate to obtain the diffusion through highly porous textile structures, but for less-porous textile materials the amount of diffusion occurring is much less than that obtained in this manner.

If one considers the case of diffusion through a highly porous bed made up with solid spheres and compares it with the analogous case of conduction, the picture is that of conduction through a continuum of good conductor with spheres of insulator interspersed in the good conductor. Maxwell[2] gave the following equation for these conditions:

$$k = k_s \frac{1 - \left(1 - a\dfrac{k_s}{k_p}\right) b}{1 + (a-1)\,b}$$

$$\text{where} \qquad a = \frac{3k_s}{2k_s + k_p}, \quad b = \frac{v_p}{v_s + v_p}$$

where k_s is the conductivity of the solid—the good electrical conductor; k_p is the conductivity of the pores—the spherical air spaces in the good conductor; v_p and v_s are the relative volumes of pore and solid.

For the case of diffusion the suffixes must be interchanged, that is, the interspersed spheres are the solid—thus $b = (1-\varepsilon)$. Assuming the diffusion through the solid is zero, this leads to $D/D_0 = 2\varepsilon/3 - \varepsilon$. In Fig. 1 experimental data due to Penman[3] for particulate systems are plotted, and it can be seen that curve B based on Maxwell's equation gives the general shape of the curve followed by the experimental points. Penman suggested that $\dfrac{D}{D_0} = \dfrac{2}{3}\varepsilon$, and it can be seen that, when ε is small, the above expression tends to this value. Maxwell's equation applies strictly only for high porosities, but it nevertheless shows good agreement with points from experiments using beds of glass spheres and beds of sand where the porosity is quite low. The line $D/D_0 = \varepsilon$ has been drawn on Fig. 1 and gives a first approximation to the results.

If one considers diffusion through the gap between two parallel solid cylinders, values of D/D_0 may be calculated for various spacings of the cylinders. A relaxation method has been used to compute such values. When the cylinders are interwoven by other cylinders perpendicular to them the porosity can be

calculated as shown by Pierce[4], who considered such a geometrical configuration in connexion with textiles. In Fig. 2 the curve relating D/D_0 and the porosity obtained in this manner is given. Some experimental data due to Robinson and Topp[5] for the diffusion of water vapour through leather are compared with the curve, and it can be seen that there is reasonable agreement. The collagen fibres in leather are interwoven so that the model used is a suitable one. When the parallel cylinders touch, diffusion is no longer possible but there is still a value of porosity. Thus the curve has an intercept on the porosity axis and differs in this respect from the curve for spheres (Fig. 1)—when the spheres touch there is still a path around them for diffusion. In a woven structure the parallel cylinders cannot touch along their entire length and thus there will always be some diffusion. This is probably the reason why the experimental points for leather are to the left of the curve.

So far as textiles are concerned the model fits the case of the woven yarns. The fibres in the yarns are twisted together so that a direct path through a yarn via gaps between fibres is unlikely. If one assumes that there is no diffusion through the yarns and applies the case of the parallel cylinders to the yarns only, then the curve given in Fig. 3 results. The values have been obtained using the average porosity of yarns found by Pierce to apply to all cotton yarns in woven fabrics. Experimental data for textiles due to Fourt and Harris[6] is compared with the curve and it can be seen that there is again reasonable agreement.

It has thus been possible to obtain values for diffusion through porous materials from theoretical considerations even in the case of textile structures. These latter have often given anomalous results when suggested equations for permeability have been applied to them.

GENETIC POLYMORPHISMS IN THE EGG ALBUMEN PROTEINS OF THE DOMESTIC FOWL

By I. E. LUSH
Agricultural Research Council Poultry Research Centre, Edinburgh 9

RECENTLY, Sibley and Johnsgard[1], using paper electrophoresis, indicated that they had observed differences in the protein 'profiles' of egg albumen between hens of several breeds. With starch gel[2] it has been possible to establish the existence of consistent differences between the electrophoretic patterns of the albumen proteins of individual hens from sixteen small closed populations. It has further been found possible to classify these differences and to accumulate sufficient genetic results for a tentative explanation of their inheritance.

The thin albumen from eggs which had been kept up to four weeks at 4° C. was drained into muslin-covered beakers and then used for electrophoresis without any treatment, absorbed on to filter paper inserts. The storage had no effect on the electrophoretic analysis. The discontinuous buffer system of Poulik[3] was used, slightly modified (gel: 0·076 *M tris*, 0·005 *M* citric acid; *p*H 8·65. Electrode vessels: 0·3 *M* boric acid, 0·1 *M* sodium hydroxide *p*H 8·81). Gels were stained overnight with 0·005 per cent nigrosine or with 1 per cent naphthalene black 12*B* for 15–30 min., and photographed by transmitted light. Nigrosine reveals the pre-albumins better than does naphthalene black.

Eggs from the sixteen closed populations listed in Table 1 were investigated. All except the Bush Crossbred population have been subjected to some degree of selection or inbreeding, or both. The Bush Crossbred population is the F_2 generation of a 4-way cross involving commercial birds of four breeds; White Leghorn, Rhode Island Red, Indian Game and Light Sussex. The Jungle Fowl have been maintained as a small flock of 12–15 birds for about eight years at the Ministry of Agriculture Veterinary Laboratory, Lasswade. The Wicob White Leghorns are a flock of very heterogeneous origin kept at the School of Agriculture, Cambridge. The brown Leghorn, *Q* and Bush Crossbred are fed on Poultry Research Centre (P.R.C.) breeder mash[4], and the others on comparable standardized diets.

The Albumen Phenotypes

Considering the electrophoretogram as a whole, all but one of the 470 hens tested during a period of six months lay eggs that fall into one or other of nine distinct albumen phenotypes. 67 hens have been tested twice and 6 hens six times or more, and all except one hen described below have been consistent in their egg albumen phenotype. The albumen types differ in one or more of three separate regions of the electrophoretogram, designated I, II and III. Fig. 1 is a starch-gel electrophoretogram, which has been stained with naphthalene black, of albumen from five different eggs which between them show all the elements of variation that have been found. Sample 1 is from the Large Egg population, samples 2 and 3 from Red Plumage, sample 4 from Breeding, and sample 5 from Bush Crossbred. The wide range of intensities of the stained fractions makes photography unsatisfactory and a clarifying diagram has been added.

The two pre-albumins visible with nigrosine staining are marked in Fig. 1. One is barely separated from the main ovalbumin complex and the other lies along the brown buffer boundary referred to by Poulik[3].

Region I. Ovalbumin has been shown to consist of three components differing in phosphorous content[5]. The question of whether the variation to be described in region I of the gel involves ovalbumin itself or one or more closely adjacent proteins is left open by the use of the purposely non-committal symbol I. The same argument applies to the other regions in which the pattern varies, in both of which the particular protein involved is unknown. Region I presents two alternative variants. In I.*A*, fractions 6 and 7 are present and fraction 5 cannot be detected. In I.*b*, fractions 6 and 7 are absent, fraction 5 clearly present and the main ovalbumin complex of fractions 3 and 4 travels slightly faster than in I.*A*, although this last effect is sometimes obscured by distortion of the

electrophoretogram. In Fig. 1, sample 4 is I.*b* and the rest are I.*A*.

Region II. Three variants have been found, involving fractions 9 and 10. In II.*A*, fraction 9 is present and fraction 10 is absent, in II.*AB* both fractions are present, and in II.*B*, fraction 9 is absent and fraction 10 present. In Fig. 1, sample 5 is II.*B*, sample 3 is II.*AB* and the rest are II.*A*. The diffuseness of fractions 9 and 10 makes it difficult to judge their intensity of staining by eye, but within a population that contains all three variants both fractions seem more strongly stained when they occur alone than when they occur together.

Region III. This also shows three variants. In III.*A*, fraction 12 is strongly present and fraction 14 is faint. In III.*AB* both are fairly strong, with 14 usually slightly stronger than 12. In III.*B*, fraction 12 is absent and 14 strongly present. In Fig. 1, sample 2 is III.*A*, sample 3 is III.*Ab* and the rest are III.*B*.

Several of the protein fractions have a very distinctive shape and character. Fraction 11, which tends to be obscured by 10 and 12, is rather variable in position but usually runs just ahead of fraction 12 and never behind it. The amount of some of the fractions, as judged by staining intensity, appears to be subject to quantitative genetic variation between populations, subsidiary to the phenotypes described above. For example, in Intensity and Bush Crossbred eggs, fractions 9 and 10 are typically stronger than in eggs from elsewhere, and in the Bush Crossbred eggs fraction 14 was also unusually strong (Fig. 1, sample 5). Within the Breeding line fraction 18 is weaker in some individuals than in others (Fig. 1, sample 4). Wilcox and Cole[4] found that the lysozyme concentration in egg albumen is amenable to selection both up and down, so quantitative differences are to be expected. The age of the hen and the position of the egg in the clutch seem to be without effect on the albumen phenotype. The first three eggs of one Large Egg × Breeding F_1 pullet gave a typical I.*A*, II.*A*, III.*B* pattern.

The distribution of the regional variants in the current generation of hens from sixteen closed populations is listed in Table 1. Of the nine phenotypes found so far, five can be read directly from Table 1 in those populations that vary only in one region, two others are recorded in Table 3 and the remaining two (I.*A*, II.*AB*, III.*AB* and I.*A*, II.*B*, III.*B*) were both present in the Bush Crossbred and Q populations.

Genetical Data

The genetical data suggest that the variation at the three regions is caused by segregation at three corresponding loci, two alleles segregating at each locus.

In region I the hypothesis of two alleles at a sex-linked locus was at first suggested to explain the two variants, but it had to be abandoned in the face of the pedigree from the Intensity line summarized in Table 2. If the locus is sex-linked, then in order to produce offspring both I.*A* and I.*b* the sire (being the homogametic sex) must be heterozygous, and the two variants should be present in approximately equal numbers. On this hypothesis the observed distribution would be very improbable ($\chi^2 = 9{\cdot}39$, $P < 0{\cdot}005$). Unfortunately, the dams of the two I.*b* offspring died too soon to be tested, but the argument is still valid. Several I.*A* and I.*b* dams have produced daughters of both types. Therefore locus I cannot be borne on a *W* chromosome.

Table 2. EGG ALBUMEN PHENOTYPES IN A HALF-FAMILY FROM THE BROWN LEGHORN INTENSITY LINE

Sire	Phenotypes of dams	Phenotypes of offspring	
		I.*A*	I.*b*
Cock. *G.* 3839	(dead)	3	
	I.*A*	5	
	I.*A*	4	
	(dead)	1	1
	(dead)	3	1

Since only two variants have been seen in region I, an autosomal locus with one allele dominant over the other must be postulated. It will be shown here that the allele determining the I.*A* variant is dominant over the allele determining the I.*b* variant, and it is proposed that the dominant allele be symbolized by I^A and the recessive allele by I^b. The heterozygote, I^A/I^b, hen would then lay eggs of type I.*A*.

F_1 hybrids between several of the Poultry Research Centre selected lines have been produced in the course of a programme of work on heterosis in this laboratory. Of these, 34 F_1 hens from the following crosses have been tested: Breeding × Large Egg, and its reciprocal; Breeding × Red Plumage, and its reciprocal. All 34 hens laid eggs with I.*A* albumen. If I^A is dominant over I^b, then I^b can only be present in the Red Plumage and Large Egg lines in heterozygotes, in the cocks, or in the untested hens (less than 5 in either line), and I^A must be the more frequent allele in these two populations. It would then be expected that most of, or even all, the hybrids with Breeding would be phenotypically I.*A*, which they are. If I^b is dominant over I^A, then the absence of I.*b* hens among the hybrids is inexplicable. 8 of the hybrids came from Breeding dams known to be I.*b*. If I^b is dominant, these dams must be heterozygotes and their progeny should approximate to a 1.I.*A* : 1.I.*b* ratio. The

Table 3. Distribution of Egg Albumen Phenotypes in the Brown Leghorn Breeding Population

Pooled data from the current generation and the surviving members of the three previous generations

Variants	Variants II.*A*	 II.*AB*	 II.*B*	Totals
I.*A*	26	5	0	31
I.*b*	48	27	2	77
Totals	74	32	2	108

observed absence of I.*b* hens among the 8 hybrids makes this hypothesis untenable ($\chi^2 = 6{\cdot}12$, $P < 0{\cdot}02$).

In region II, fractions 9 and 10 can be considered separately or together. If separately, it can be postulated that the presence and absence of fraction 9 are determined by two alleles at one locus, one allele being dominant over the other. Fraction 10 could be determined in the same way at a different locus. If together, it can be postulated that each of the two protein fractions is the product of a different one of two alternative alleles at only one locus, locus II; in other words, a one gene equals one fraction (= one protein) relationship. The available data are compatible with any of these hypotheses, but the last seems most acceptable for the following reasons. No egg albumen which lacks both fractions 9 and 10 has been found. Fractions 9 and 10 resemble each other in shape and diffuseness, and differ in these respects from most of the others. Finally, as was mentioned before, when both fractions are present there seems to be less of them than when they are present separately, so long as the comparison is made within a population. If the single-locus hypothesis is confirmed, the alleles determining the presence of fractions 9 and 10 may be symbolized by II^A and II^B respectively.

Table 3 shows the distribution of phenotypes in the Breeding line, both the present generation and the surviving members of the three previous generations. There is a slight but not significant association between I.*A* and II^A ($\chi^2 = 5{\cdot}01$, $P > 0{\cdot}05$). In both the present and the pooled Breeding line data the distribution of the region II variants does not differ significantly from a Hardy-Weinberg distribution.

In region III the genetical data and the electrophoretic variation resemble region II and the same arguments apply, with one complication. Let us postulate a locus III at which two alleles, III^A and III^B, determine the presence of proteins 12 and 14 respectively. In the homozygote III^B/III^B, only protein 14 is synthesized, in the heterozygote III^A/III^B both proteins are present, and in the other homozygote III^A/III^A only protein 12 should be present, yet in fact in variant III.*A* protein 14 seems to persist (see Fig. 1). However, there is no reason for supposing that the electrophoretic separation is perfect, and the anomaly would be explained if fraction 14 were shown to be a mixture of two genetically unrelated but electrophoretically superimposed proteins, the major one subject to the genetic variation, and the minor one constantly present in every egg throughout the population. This would also explain why in the heterozygote III^A/III^B (giving variant III.*AB*), when both proteins might be expected to be present in equal strength, fraction 14 nearly always appears stronger than fraction 12.

If, and when, chemical identities are given to the proteins involved in the variations described, loci I, II and III can be replaced by more informative symbols. Fractions 3 and 4 are almost certainly ovalbumin[7]. Unpublished work, in collaboration with Dr. W. N. M. Ramsay, of the Department of Biochemistry, University of Edinburgh, using iron-59, has shown that small amounts of added iron are bound almost exclusively by fractions 17, 16 and possibly 15, which can therefore be included in the term conalbumin. Fraction 19 is lysozyme.

It has been mentioned that one hen was not consistent in its egg albumen phenotype. This bird, *F* 3230 from the Poultry Research Centre Intensity line, hatched in June 1957, was used between April 25 and June 14, 1960, in a control experiment to test the effect of egg storage on albumen phenotype. All 12 of the eggs used were I.*B*, II.*A*, III.*B*, and it was noticed that the lysozyme fraction was unusually variable in amount. Between August 30 and October 6 the hen laid 8 eggs, and in all but the second of these fraction 12 was present but usually less strongly than in a typical III.*AB* variant. In the last two eggs, lysozyme had almost vanished and ovalbumin was becoming progressively weaker.

Nothing resembling this has been seen in any of the other several hundred eggs examined in this work, all of which have been readily classifiable without the slightest hesitation into one or other of the phenotypes described. The anomalous changes may be caused by a pathological condition in the oviduct.

This work was done during the tenure of a British Egg Marketing Board studentship. I am grateful to Dr. A. W. Greenwood for providing facilities and to Drs. J. H. Sang, D. J. Bell and J. S. S. Blyth for helpful discussions and advice. The Jungle Fowl eggs were kindly given by Dr. J. E. Wilson.

(*Note added in proof.* The above results were obtained with freshly made starch gels. With gels which have been stored overnight at room temperature, it has been found possible to discriminate between the albumens of hens of genotypes I^A/I^A and I^A/I^b. These findings will be described in detail elsewhere.)

REPRODUCTION IN THE GREAT GREY KANGAROO

By PHYLLIS E. PILTON

Department of Zoology, University of Adelaide

TWO female great grey kangaroos (*Macropus major* Shaw) collected at Padthaway, south-east South Australia, in late October 1959, had a new corpus luteum in one or other ovary. At least one of these had recently mated, as spermatozoa were seen in glands of the sectioned uterus. In the same area females were pregnant, or had early pouch young, in late December 1959. At Blanche Town, South

Australia, females were pregnant in early November 1958. On Kangaroo Island, South Australia, the insular form of the great grey kangaroo (*M. major fuliginosus* Gould) was observed mating in late December 1956. At Padthaway, in October and December 1959, breeding females were suckling advanced young which had left the pouch, and in March and April 1960, females with hairless pouch young were suckling an older young out of the pouch. A single female, collected on Kangaroo Island in February 1958, had a hairless pouch young and a large young at heel which was being suckled. Three females in captivity at National Park near Adelaide, South Australia, were examined. In early November 1960, two were suckling young at heel and one of these had an early pouch young. The other gave birth to a young later the same month. The third National Park female had an early pouch young and was suckling a young at heel in mid December. In April 1958, at Blanche Town, and in August 1960, at Padthaway, females had large pouch young, but were not suckling young at heel.

The gestation period of the great grey kangaroo is 38–39 days[1]. The ages of pouch young, collected with their mothers in the wild, were unknown, but approximate ages were assigned by comparing them with young of known ages of the red kangaroo (*Macropus rufus* Desm.). New-born young of the two species are approximately the same weight (about 0·9 gm.) and the adults are approximately equal in size. It was assumed that growth-rates are comparable in the two species. All 11 Padthaway young examined were conceived between early October and early January and the three National Park young in early September and early and late October. The two Blanche Town young and the single Kangaroo Island young were conceived in November.

The observations on post-œstrous and pregnant females and on pouch-young indicate a breeding season from early September to early January. The great grey kangaroo breeds in December in northern New South Wales[2]. The association between mother and offspring is particularly long: suckling, in and out of the pouch, lasts at least 14 months in the Padthaway area.

Corpora lutea of pregnancy were reduced in size in March, two months after the end of the breeding season, and absent in August. However, three females taken in the breeding season had two corpora lutea of different ages. This indicates that the great grey kangaroo is polyœstrous, but I have so far been unable to determine the length of the œstrous cycle by taking daily vaginal smears of captive females.

Sharman[3] stated that lactation-controlled delayed implantation was a feature of reproduction in two species of macropod marsupials and probably occurred in at least three others. It is now known to occur also in the macropods *Protemnodon irma*[4], *Thylogale thetis*[5], *Macropus robustus*[6], *Lagostrophus fasciatus* and *Bettongia lesueur*[7]. In those species having delayed implantation that have been thoroughly investigated the gestation period is shorter than, but nearly equal to, the length of one œstrous cycle. During the period at which a quiescent, unimplanted blastocyst occurs in the uterus there is a small corpus luteum, formed at a post-partum ovulation and called the corpus luteum of lactation, in one ovary. Growth of the corpus luteum of lactation and development of the blastocyst occurs following premature loss, or removal of, the young from the pouch[3]. Female great grey kangaroos carrying young in the pouch did not have corpora lutea of lactation, and a female from which the young was experimentally removed, and which was known to have been with males at parturition, did not produce another young.

Females taken early in the breeding season at Padthaway and Blanche Town had new, developing corpora lutea in the ovaries and the uteri were in the proliferative phase. One of these, which had evidently recently mated, had the anterior vaginal canals and median vaginal culs-de-sac enlarged and filled with a creamy substance containing abundant sperm. In the others the occurrence of earlier mating could only be verified from the presence of sperms in the uterine glands. Similar conditions occur after œstrus and mating in other species of macropod marsupials[3]. Two females in late pregnancy, with embryos 19·3 and 22 0 mm. greatest length, had enormously distended anterior vaginal canals filled with creamy substance containing abundant sperm. The canals were less distended in a female with a new-born young (greatest length 21·5 mm.). No sperms were found in the vaginal canals of this female, but they occurred in the uterine glands. Copulation had thus recently occurred in these three females, but none had Graafian follicles containing mature eggs and none had recently ovulated. Mitotic activity was seen in the uterus of the female with the 22·0 mm. embryo but was not seen in the uteri of the two other females. The seminal fluid was evidently not left in the reproductive tracts from earlier inseminations because it was absent from females with earlier embryos measuring 9·5 and 19·0 mm. A little seminal fluid but no sperm was found in an animal with a 5·5 mm. embryo. No seminal fluid was found in the tract of one female with an embryo measuring 23·5 mm. greatest length.

It was concluded from these observations that delayed implantation is not a normal feature of reproduction in the great grey kangaroo as it is in related macropod marsupials. The œstrus which occurs near the end of pregnancy may be the result of possible high levels of extra-ovarian hormones secreted during pregnancy. As it is not accompanied by ovulation, it cannot be followed by fertilization as is the post-partum œstrus in related species. The possibility that this sterile copulation is the equivalent of post partum copulation in other species and that in the great grey kangaroo the gestation period has been extended beyond the limits of the œstrous cycle will be investigated next breeding season.

This investigation is based on a total of twenty-six adult females. Funds for the project came from Commonwealth of Australia Research Grants to Universities and from a generous grant from the Nuffield Foundation. The work was supervised by Mr. G. B. Sharman, who provided some of the specimens, with information on their history.

ANALYSIS OF THE CROSS-REACTION BETWEEN TWO STRAINS OF TOBACCO MOSAIC VIRUS

By Prof. IRVING RAPPAPORT

Botany Department, University of California, Los Angeles

DIFFERENT virus strains are considered to be related antigenically if an antiserum prepared against each strain reacts in some way with the others. This combination, which is known as a cross-reaction, serves as the foundation for all strain relationship studies.

Although there is usually little or no controversy with the serological findings themselves, the symbolic representation of the results often do lead to dispute. This is understandable when one considers that cross-reactions may imply either of the following interpretations: (1) Each virus strain may be a mosaic possessing a number of distinct antigenic components. One or more of these components may be shared with other strains. Thus, a fraction of the antigenic surface may be identical on all strains displaying cross-reactivity, while the remaining antigenic components may be unique, and specific for particular strains. (2) Each virus strain may possess but a single kind of determinant which, however, is structurally similar to that found on related virus particles. In this case, strains are related if the spatial configurations of their surface antigens are similar to each other. They need not be identical to those found on related strains. These two cases are known respectively as the mosaic and single determinant case. They may, of course, be combined, that is, some sites may be identical on two strains while others may only be related. For our initial consideration here, however, the two cases will be treated as alternative extremes.

Frequently, in cross-reaction studies, it is not clear which of these alternatives the author has in mind, even though it is common for one or the other to be chosen almost arbitrarily. This is a problem which has been faced time and time again, and has been discussed at length by many investigators. For this reason, no attempt will be made in this article to review the subject of cross-reaction. The reader is referred instead to such general sources of information as Landsteiner[1], Kabat and Mayer[2], Race and Sanger[3], Burnet and Stanley[4], Matthews[5] and to an excellent summary of the problem from the immuno-geneticist's point of view by Owen[6]. The purpose of this article is to present a method of analysis which promises some success in distinguishing between the alternatives.

To a large extent, the difficulties encountered can be attributed to the reagents used for measurements, that is, the antisera. Both the mosaic and single determinant scheme require that the antisera which are produced, following immunization with single virus strains, are heterogeneous. The nature of this heterogeneity, however, is different for each case, so that two classes of antibody heterogeneity need to be considered.

In the first class, applicable to the mosaic case, discrete populations of antibodies are elicited, each of which combines specifically with the particular inciting antigen, and not with any of the others. These antisera are mixtures containing, at most, as many different kinds of antibodies as there are unique surface antigens on the virus used in the inoculum. Cross-reaction occurs when one of these discrete populations of antibodies combines with the surface of a related strain possessing an antigen identical to that of the immunizing strain.

In the second class, a single population of antibodies is present in each antiserum. These populations, although stimulated in response to single antigenic determinants, contain antibody molecules with broadened combining powers, capable of reacting with antigens that are structurally similar to the homologous one. The two antigenic cases and their accompanying antibody classes are summarized in Table 1.

Table 1. Possible Relationships between Two Virus Strains showing Cross-Reaction

Case	Strain	Antigenic surface	Antibodies
1. Mosaic	1	*A* ▨*B*	*a*, *b*
	2	*A* *C*	*a*, *c*
2. Single determinant	1	*A*	*a*
	2	A^1	a^1

This is the simplest example in which only two strains are analysed. Theoretically, for each new virus strain studied an additional antigen and corresponding antibody could be added under the mosaic concept whereas another antigen, again similar to A or A^1 would be assumed in the single determinant case.

For simplicity, the mosaic and the single determinant cases are described separately, although they need not be mutually exclusive. The two may well be represented in any one virus as already mentioned. In addition, the number of different antigenic determinants shown is the absolute minimum. Many more may be required to characterize a particular virus, depending on the complexity of the data and the number of different virus strains examined.

Although for practical purposes of virus identification and classification, it may be of little consequence to discriminate between the mosaic and single determinant scheme, the differences are nevertheless important. Each scheme leads to a distinct view both of the physico-chemical structure of the virus surface and of the amount of genic information required for the transmission of these characteristics. Thus, on theoretical grounds, the differences are significant enough to warrant all efforts to distinguish between the two.

Because of the long and successful history of the mosaic concept as applied to cellular and bacterial investigations, it is not surprising that this scheme

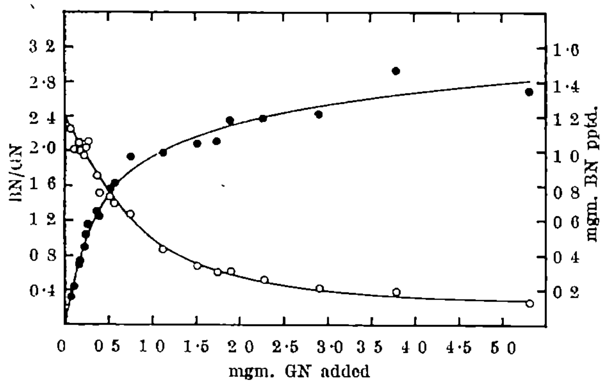

Fig. 1. Quantitative precipitin reaction. *U*2 vs. anti-*U*2 antiserum pool 17–18. Data are for antibody N precipitated in antibody excess to equivalence, and corrected to 1·0 ml. undiluted antiserum. Closed circles—antibody N (BN) precipitated. Open circles—ratio of antibody N to antigen N (BN/GN)

has played the dominant part in virus classification On the other hand, scheme 2, that of the single determinant, deserves more serious consideration, particularly because it has been demonstrated that a variety of immunological systems conform to the single determinant hypothesis. This by no means suggests that the mosaic hypothesis as applied to virus classification is inapplicable. It does, however, suggest that one observes some restraint in assigning a series of code letters to a virus strain in order to indicate its antigenic similarities or differences with related strains without the requisite evidence.

In those cases where the reactive sites are chemically defined the required evidence can be obtained, and proper relationships established, from a qualitative analysis of cross-absorption data. Many classical examples of such analyses are given by Landsteiner[1]. Unfortunately, the chemical nature of the antigenic determinants on the surface of virus particles are as yet undefined, and qualitative cross-absorption studies on a system with chemically unknown antigenic determinants are incapable of distinguishing between the two cases. Nevertheless, a quantitative analysis of the cross-reaction curves may resolve the issue. As a case in point, the quantitative data obtained from the cross-reaction between two related strains of tobacco mosaic virus, *U*1 and *U*2, will be described.

The homologous precipitin reaction for *U*2 and rabbit anti-*U*2 is shown in Fig. 1. The reaction is characterized by a steep rise in the amount of antibody nitrogen precipitated where the concentration of antigen nitrogen added is small. This region is followed by a more gradual and prolonged increment in antibody precipitated until the equivalence zone is reached. The ratio of antibody nitrogen (BN) to antigen nitrogen (GN) combined consequently falls precipitously at first, and then less so as more antigen nitrogen is added.

The more common equations for describing the quantitative precipitin reaction are inadequate to account for these data. Although other equations can be fitted to the data, they all suffer from the same shortcoming. They assume that only a single kind of antibody is combining with one kind of antigenic configuration. In the present case, we are concerned as well with the possibility of diverse antibody molecules reacting with a number of different antigenic sites on the same virus particle. For this reason, until proved otherwise, the precipitin curve shown in Fig. 1 is assumed to be a composite of at least two reactions, the sum of which adds up to the total shown.

Before proceeding with the analysis of the precipitin curve, it is well to point out that this tobacco mosaic virus/anti-tobacco mosaic virus system appears immunologically homogeneous according to Kendall's criterion[7]. A clear equivalence zone is observed where neither antibody nor antigen (or only minute traces of each) is detected in the supernatant liquid after the precipitates have been removed by centrifugation. This implies, by definition, that all *U*2 particles are identical with respect to antigenic characters and that there are present no detectable amounts of contaminant virus or other antigenic units and corresponding antibodies different from the bulk virus and antibody population studied in the reaction. This point cannot be over-emphasized. In those cases, for example, where it is demonstrated that different antigenic determinants are carried on distinct and separable molecules, the following analysis does not apply.

The Mosaic Case

Considering the mosaic hypothesis first, a resolution of the precipitin curve into two component parts can be accomplished if the following conditions be assumed :

(1) There are two discrete kinds of antigenic sites on the virus called *A* and *B*. Each type makes up some specified fraction of the total number of combining sites.

(2) Each type of antigenic site in turn stimulates the production of an antibody population which is specific ; so that anti-*A* (*a*) reacts only with *A* and anti-*B* (*b*) only with *B*.

(3) No interference is encountered during precipitation by either antibody type. The reactions of anti-*A* with *A* and anti-*B* with *B* occur independently of each other and progress to a final state which can be predicted from the concentrations of each antibody population and the two kinds of antigenic sites described in (1).

(4) In the presence of an excess of both antibodies, the maximum number of respective virus valences will be satisfied, and within this range of antibody excess the amount of antibody precipitated will conform to the quadratic equation proposed by Heidelberger and Kendall.

The observed shape of the precipitin curve imposes certain restrictions on the calculations of the fraction of antigenic sites assigned to *A* and *B* and on the concentration of the respective antibodies. With this limitation in mind the precipitin curve shown in Fig. 1 was resolved to a reasonable degree, by trial and error, into the components appearing in Figs. 2 and 3. This resolution is unique, for no other combination of two precipitin curves will satisfy the data better. From the maximum antibody-antigen ratios obtained in Fig. 3, the fractions of the total antigenic sites which are *A* and *B* are estimated. Approximately 0·83 (2 ÷ 2·4) are *A* and 0·17 (0·4 ÷ 2·4) are *B*.

In Fig. 2, it is seen that the amount of anti-*A* in combination with *A* rises steeply with small additions of virus, since most of the viral surface is *A*. With the addition of 0·55 mgm. of virus nitrogen all the anti-*A* is bound. From this point on, a constant amount of anti-*A* is found in the precipitate in addition to the increasing amounts of anti-*B*. The equation for the first part of the *A*/anti-*A* precipitin

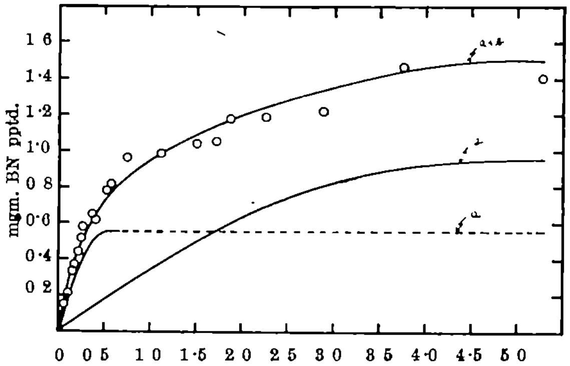

Fig. 2. Quantitative precipitin reaction. *U*2 vs. a hypothetical antiserum containing a mixture of antibodies *a* and *b*. The curves relate the amount of antibody N contributed individually by *a* and *b* to the precipitate and also the sum of the two. The open circles are the experimental points for antibody N precipitated taken from Fig. 1

curve is $\mathrm{BN}_A = 2{\cdot}0\ \mathrm{GN} - 1{\cdot}82\ \overline{\mathrm{GN}}^2$, where BN = antibody nitrogen precipitated and GN = antigen nitrogen precipitated.

The combination of *B* with anti-*B* progresses over a more extensive range since relatively little of the virus surface is *B*. Therefore, much larger amounts of virus nitrogen are required to bring the *B*/anti-*B* system to equivalence. At the point of equivalence for the *B* antigen the entire complex system reaches equivalence. Beyond this, further additions of virus will lead to an antigen excess zone. The equation describing the *B* system is $\mathrm{BN}_B = 0{\cdot}4\ \mathrm{GN} - 0{\cdot}042\ \overline{\mathrm{GN}}^2$, where the symbols have the same meaning as before.

The gross precipitation observed is the sum of the two quadratic equations to the point of equivalence for the *A* system, or $\mathrm{BN} = 2{\cdot}4 - 1{\cdot}86\ \overline{\mathrm{GN}}^2$. Beyond this point $\mathrm{BN}_{\mathrm{total}} = \mathrm{C}_A + 0{\cdot}4\ \mathrm{GN} - 0{\cdot}042\ \overline{\mathrm{GN}}^2$, where C_A is a constant equal to the maximum anti-*A* content of the antiserum. In this case $\mathrm{C}_A = 0{\cdot}55$ mgm.

Granted such a complex precipitating system, certain predictions can be made concerning any cross-reaction observed with this antiserum and related virus strains. The following cases are then logical consequences of the mosaic hypothesis :

Case 1. Both *A* and *B* are present on the test strain. In this case cross-absorption would remove all anti-*A* and anti-*B*. The test strain would be judged on this basis to be identical to the homologous. The test strain may not be identical in quantitative tests, if it were shown that either the ratio of *A* to *B* were different or the combined total of *A* and *B* was more or less than on the homologous strain, or that an antigen *C* was present in addition to *A* and *B*.

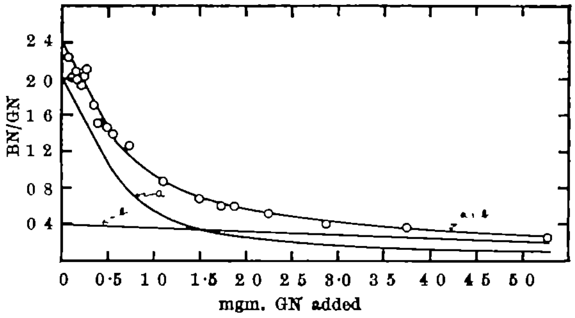

Fig. 3. Quantitative precipitin reaction. *U*2 vs. a hypothetical antiserum containing a mixture of antibodies *a* and *b*. The curves relate the ratios of antibody N to antigen N found in the precipitates individually for *a* and *b* and for the sum of the two ratios. The open circles are the calculated values taken from the experimental results shown in Fig. 1

A quantitative analysis of the cross-precipitin curve would not detect '*C*' in these circumstances, but would reveal whether or not the total number of combining sites for anti-*A* and anti-*B* were different from that of the homologous strain.

This information would be obtained by noting any change in the maximum antibody-antigen ratio. A value of less than 2·4 would indicate fewer identical sites on the related strain, and thereby suggest the possibility of an additional antigen not found on the homologous strain. Alternatively, such data may be interpreted as suggesting a decreased surface-to-volume ratio for the virus particle with a concomitant reduction in the total number of antibody molecules that can be attached to the surface of the virus. An antibody–antigen ratio significantly greater than 2·4 would almost certainly imply a smaller virus particle with identical surface antigens.

Case 2. *A* is present on the test strain, but *B* is not. Cross-absorption would remove approximately one-third of the antibody. The two-thirds remaining, or anti-*B*, would react with the homologous strain.

If the test strain possesses no antigenic grouping other than *A*, the antibody–antigen ratio in the cross-precipitin curve would extrapolate to 2·4. If the test strain possesses other non-related antigenic groups and the size and shape of the virus particle were identical to the homologous strain, then the extrapolated ratio would be less than 2·4, in proportion to the fraction of the total which is *A*.

The absorbed antiserum, which now contains only anti-*B*, will react with only that portion of the surface of the homologous strain which is represented by antigen *B*. Therefore, after cross-absorption the precipitin curve for the homologous reaction should always show a decrease in the maximum antibody–antigen ratio.

Furthermore, if the cross-reactive antibody (anti-*A*) is dissociated and recovered from the heterologous precipitate it, too, when treated with the homologous strain, should reveal a drop in the antibody–antigen ratio. The two ratios, the one obtained with the non-absorbed antibody plus the one obtained with the dissociated antibody, should add up to 2·4.

Case 3. *B* is present on the test strain, but not *A*. The analysis for this case is identical to Case 2.

One further consequence of a multiple system is that partial absorption of the antiserum with its homologous strain should also lead to a fractionation of the antiserum. For example, from Fig. 2 a small amount of antigen nitrogen could be added, sufficient to precipitate all of anti-*A* but only a part of anti-*B*. The remaining unprecipitated antibody would then react in a different way (revealed by a drop in BN/GN ratio) from both the whole unabsorbed antiserum and the antibody recovered from the precipitate after dissociation.

The Single Determinant Case

Two different and detailed analyses of the tobacco mosaic virus/rabbit anti-tobacco mosaic virus precipitin curve, based on the assumption that a single population of antibodies was reacting with one kind of antigenic configuration, have been presented elsewhere[8,9] and so will not be repeated here. For purposes of the present discussion, it is sufficient to note that under the single-determinant hypothesis, none of the preceding attempts to fractionate the antiserum into two discrete and unrelated antibody populations would be successful. Cross-precipitation with related strains would be characterized solely by a drop in titre, since only a portion of the antibody population would be expected to possess any reactivity towards the related antigen. In general, the more perfect the correspondence between the test antigen and the homologous one, the larger the antibody fraction which will react, and the greater will be the similarity in the precipitin curves. No change in the maximum antibody–antigen ratio would be expected either in the cross-reaction (provided again that the surface-to-volume ratio of the heterologous strain is the same as the homologous one), or in the homologous reaction after complete heterologous absorption. Furthermore, no fractionation again into two unrelated antibody populations would be accomplished by partial absorptions with the homologous virus.

A note of caution should be introduced at this point, since such cross-, partial-, or multiple-absorptions have been known to reveal univalent antibody[8]. When present in an antiserum, these univalent antibody molecules commonly co-precipitate with the aggregates initially formed by the divalent antibody and the multivalent antigen. Characteristically, such additions alter the shape of the precipitation curve from a simple quadratic form to one resembling the tobacco mosaic virus/anti-tobacco mosaic virus curves. Thus, the steep initial segment of the antibody curve shown in Fig. 1 may represent essentially the precipitation of divalent antibody, while the more extensive gently rising portion, on the other hand, may indicate the participation of co-precipitating univalent antibody. If this were true, then the precipitation curve observed with antibody dissociated from the homologous partial absorption would be qualitatively quite different from that observed for both the remaining unabsorbed antibody and the original antiserum. This was not observed. The general features of the precipitation curves were always the same as those seen in Fig. 1. Thus, if univalent antibodies were present, they contributed very little to the overall precipitation curve.

It is apparent from the foregoing that the most sensitive datum for distinguishing between the mosaic and single determinant case is the maximum extrapolated value for the antibody–antigen ratio in extreme antibody excess. Any difference in number, or kind of antigenic configuration, will be revealed by some change in the estimation of this maximum ratio. Such changes in ratio were looked for in the tobacco mosaic virus system under investigation, but were not detected.

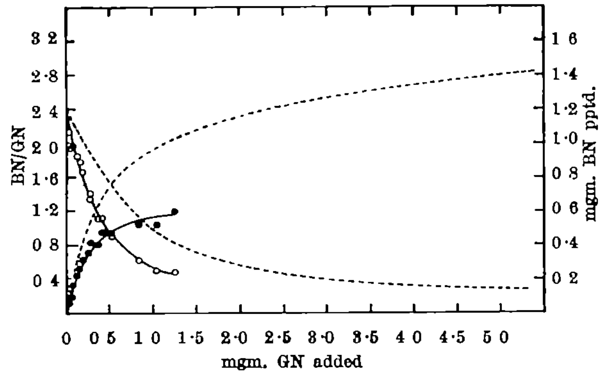

Fig. 4. Quantitative precipitin reaction. *U*1 vs. anti-*U*2 antiserum pool 17–18. Continuous lines are data for the cross-reactive virus *U*1 in antibody excess and corrected to 1·0 ml. undiluted antiserum. Closed circles—antibody N precipitated. Open circles—ratio antibody N to antigen N (BN/GN). Broken lines are the data for the homologous reaction shown in Fig. 1 drawn to the same scale for comparison

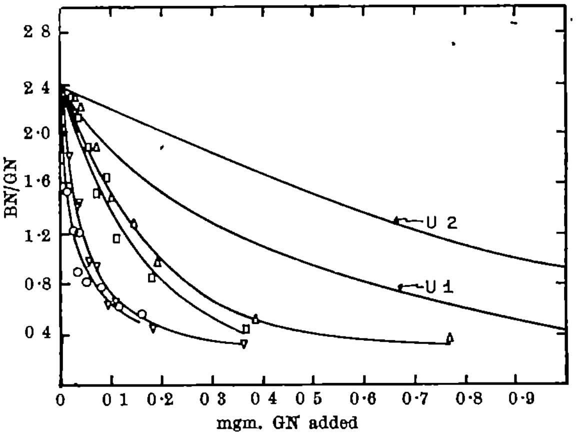

Fig. 5. Quantitative precipitation reaction. Ratios of antibody N to antigen N (BN/GN) revealed after different absorptions of anti-*U*2 antiserum pool 17–18. Lines *U*2 and *U*1 are reference lines of the homologous and heterologous reaction taken from Figs. 1 and 4 and drawn to scale. The following data are uncorrected for the different dilutions encountered: △, after complete heterologous absorption of the antiserum with *U*1 the remaining antibody was precipitated with *U*2; ▽, reaction with homologous *U*2 virus of antibody recovered after acid dissociation from *U*1 anti-*U*2 precipitate; ○, after partial absorption of antiserum with homologous virus, the remaining unabsorbed antibody was treated again with *U*2; □, the precipitate from the partial homologous absorption was dissolved in acid and antibody recovered. This antibody was reacted with *U*2

Fig. 4 relates the quantitative course for the cross-precipitation of *U*1 and anti-*U*2. Apart from the obvious diminution in the quantity of antibody precipitated by the heterologous antigen, the qualitative shape of the precipitin curve is similar to that of the homologous reaction. Furthermore, the extrapolated value for the maximum antibody–antigen ratio does not appear to be different from 2·4. Thus, the antiserum reacts with as many determinant groups on *U*1 as it does on its homologous strain, *U*2.

After complete removal of the cross-reactive antibody by absorption of the *U*2 antiserum with *U*1, the remaining antibody was treated with *U*2. The precipitin curve showed no change in the maximum antibody–antigen ratio. This suggested that no fractionation of the original antiserum, of the kind proposed under the mosaic hypothesis, was accomplished by this procedure. Other attempts to reveal unique antibody populations also failed. The complete data are presented in Fig. 5.

The reciprocal cross-reactions employing an anti-*U*1 antiserum were also investigated. The data were similar to those shown in Fig. 5, suggesting again that only a single antigenic determinant was involved in these reactions. Although this interpretation of the data is the preferred one, at least one other possibility may be entertained.

Tobacco mosaic virus is known from X-ray studies and chemical analyses to be composed of approximately 2,130 protein sub-units[10]. Each of these sub-units is presumed to be antigenic. However, the maximum number of antibody molecules that can combine with an intact tobacco mosaic virus rod has been estimated[9] to be between 700 and 1,200. Thus half or more of the antigenic surface may remain uncombined, as seen in Fig. 6, even under the most favourable conditions of antibody excess simply because of steric hindrance.

Since the experimental evidence tends to favour the notion that only one-third rather than one-half of the sub-units can be combined with antibody, the model described in Fig. 6 will be considered further. Assuming that the model is correct, it is possible to distribute two or three antigenic determinants, but no more, over the surface of the rod in such a fashion that the expected quantitative cross-absorption data would be indistinguishable from those obtained if only a single determinant were present. The different antigenic combining groups must be arranged in the precise serial order of *ABCABCABC* . . . etc., if three are present and *AABAABAAB* . . . etc., if only two are involved. These arrangements are unique. No other, or random distribution of the determinants on the sub-units would yield the same data, nor would four or more different sub-units arranged in any fashion yield comparable results. Consequently, the quantitative precipitation data are capable of distinguishing between the single determinant and the mosaic hypothesis in all cases except the two highly restrictive ones where exactly one-third or two-thirds of the sub-units are *A* and the arrangements are precisely ordered. All the combinational possibilities are described in Fig. 7.

Two general views of the precipitation of tobacco mosaic virus with rabbit antibody have now been presented. In the first and most widely accepted view of precipitation, the tacit assumption is made that in extreme antibody excess all the antigenic sites are combined with antibody. The other, as just described, is that even at best, probably no more than one-third of the antigenic sites are covered. It is under this latter view that one may entertain the notion of a mosaic antigenic structure for tobacco mosaic virus which would be extremely difficult to distinguish from one in which all of the exposed antigenic determinants were identical.

Thus, although the evidence suggesting a single antigenic determinant for tobacco mosaic virus is good, it is for the present not compelling. Positive evidence for the existence of more than one distinct exposed antigen must await a thorough serological analysis of tobacco mosaic virus sub-units of the kind prepared by Ansevin[11] and Wittmann[12]. Until then, the single determinant scheme, with its virtue of simplicity, deserves consideration. It demands the least number of unique antigenic configurations on the viral surface, and a minimum other assumptions as well. The complex results of serological cross-absorptions are charged to the antisera employed. Antibody heterogeneity resulting from immunization with single antigens is commonplace. The problem resolves, therefore, into distinguishing between complexities that stem from an immune response and those inherent in the virus structure.

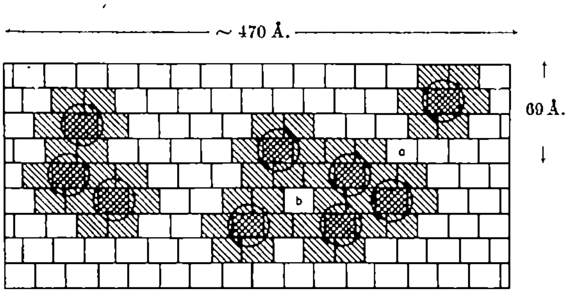

Fig. 6. A diagrammatic representation of a portion of the surface of tobacco mosaic virus showing 3 complete turns of the helix. Each rectangle represents a sub-unit 23 Å. by 29 Å. The circles represent rabbit antibody molecules (with 19 Å. short semi-axis) standing on end attached to an antigenic determinant centrally located on the cross-hatched sub-unit. The shaded areas are those that are blocked from further antibody attachments. In the upper right-hand corner, one antibody molecule exerts its influence over 6 sub-units other than the one to which it is combined. An antibody combining at *a*, will interfere with 2 sub-units not already blocked by the other antibody molecules. An antibody attaching at *b* will interfere with none that is not already blocked. This model permits a maximum combination of one-third of the sub-units with antibody molecules. (Figure taken from Rappaport, I. *J. Immunol*, 82, 526; 1959)

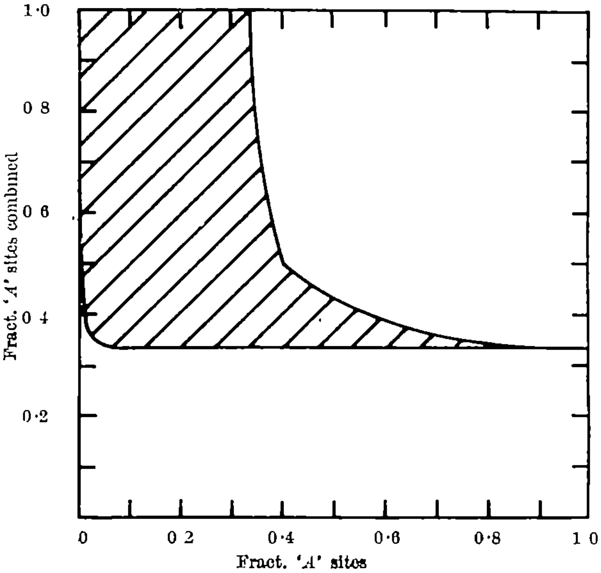

Fig. 7. The relationship between the maximum fraction of *A* sites which can be combined with antibody as a function of the fraction of sites on the tobacco mosaic virus rod which is *A*. This graph is valid for all possible sequences or arrangements of *A* sub-units making up the virus. For example, if the fraction of *A* present were 0 33 and the arrangement were ordered *ABBABBABB* . . . etc., then 100 per cent of the *A* sites could be covered with antibody molecules. If this same number of *A* sub-units were arranged side by side in a block, only 33 per cent could be combined with antibody Any random arrangement of 0 33 *A*'s among the other antigenic sites would result in a maximum combination with antibody somewhere between 33 and 100 per cent, that is, some value in the shaded area. The shaded area, then, indicates the maximum possible combinations for all distributions of *A*

I wish to thank Dr. Sam G. Widman for many suggestions during both the course of the work and the preparation of this manuscript. I also thank Dr. Ray D. Owen for his critical review of the work.

LETTERS TO THE EDITORS

COSMOLOGY

Cosmological Significance of Angular Measurements of Distant Radio Sources

THE programme of interferometric observations of distant radio sources at present being carried out by H. P. Palmer *et al.* at Jodrell Bank may prove to be of great significance for cosmology. The preliminary results recently published[1] indicate that out of 91 sources 38 were of sufficiently small angular diameter to produce measurable interference fringes at the long base line used (32,000 λ at $\lambda = 1{\cdot}89$ m.). and at least 7 had a diameter between half-power points less than 3 sec. of arc. Furthermore, these 7 were described as having "an extremely high surface brightness which is comparable with that of the intense radio source in Cygnus I.A.U. 19 *N4A*".

In the case of a steady-state universe it has been shown[2,3] that the angular diameters of sources must tend to non-zero lower limits on the observational horizon of the model ($\delta = \infty$). For a Cygnus *A* type source of colliding galaxies, Hoyle has adopted an angular diameter of 80 sec. of arc at the distance of the Cygnus source ($\delta = 0{\cdot}056$) and this leads to a horizon limit of about 4 sec. of arc. The figure 80″ is approximately the angular distance between the centres of the two radio components of the Cygnus source, so that 4″ may be taken to be the limiting half-power diameter of this source if shifted to the horizon. However, the Cygnus source has a ratio of major to minor axes approximately equal to 4, and therefore for sources of this type the average limiting diameter observed east–west would actually be nearer 2½″. It appears, therefore, that the present Jodrell Bank results are not inconsistent with the predictions for a steady-state universe.

In the case of evolutionary universes, provided we can assume that the average intrinsic distance between components of colliding galaxies does not vary significantly with epoch, predictions can be made in special cases. In the Einstein–de Sitter model the average half-power diameter of the Cygnus *A* type source specified above should not fall below a minimum value of 8½″ occurring at $\delta = 1{\cdot}25$, which is more than three times the steady-state limit of 2½″. In a Milne universe the lower limit would occur at $\delta = \infty$ and is twice the steady-state limit, that is, about 5″. In the Dirac cosmology the half-power diameter would fall to a minimum of 13″ at the relatively near point where $\delta = 0{\cdot}73$, and thereafter it would increase. Thus, all these well-known evolutionary models are placed in jeopardy by the present measurements of angular diameter.

Before applying this criterion, it is of course essential to ascertain that the sources are indeed similar to Cygnus *A*, and this can only be done for distant sources by selecting those of a surface brightness comparable to that of Cygnus *A*. According to present ideas only colliding galaxies could generate an energy flux of this high order.

In this connexion, however, attention is directed to a fact that does not appear to have been realized before, namely, that the surface brightness to be inferred for extra galactic radio sources depends strongly and explicitly on their red shift, and therefore cannot be calculated accurately from the angular diameter and apparent intensity alone, except when δ is small. Since the interpretation of any observational test in cosmology involving radio sources depends critically on what is assumed to be their luminosity function, this is evidently a matter that requires careful attention at the present time.

The formula for surface brightness may be derived as follows.

In the usual notation the general cosmological metric of homogeneous isotropic expanding world models is :

$$ds^2 = c^2dt^2 - R^2(t)\,\frac{(dr^2 + r^2d\theta^2 + r^2\sin^2\theta d\varphi^2)}{(1 + kr^2/4)^2} \qquad (1)$$

Consider a source the permanent (co-moving) spatial co-ordinates of which are (r,θ,φ). Let the surface brightness distribution function of a given element of its surface area, at the emission frequency ν and at the epoch of emission t, be $B(\nu,t)$ (W. m.$^{-2}$ (c./s.)$^{-1}$ ster.$^{-1}$). Hence the energy radiated from a surface element of proper area ΔA in the interval $t, t + dt$, in frequency-range $\nu, \nu + d\nu$, and in solid angle $d\omega$ will be :

$$B(\nu,t)d\nu dt d\omega \quad \Delta A \qquad (2)$$

Then, if $d\omega$ corresponds to 1 sq. m. at the observer who is located at $r = 0$ at the epoch of reception t_0, we know that[4] :

$$d\omega = 1/\{R^2(t_0)r^2/(1 + kr^2/4)^2\} \qquad (3)$$

Also, if the frequency-range of reception resulting from red shift is $\nu_0, \nu_0 + d\nu_0$, and if $\Delta I(\nu_0)d\nu_0$ is the rate at which energy from ΔA in this frequency-range falls on 1 sq. m. at the observer, we may express the degradation of the energy (2) due to red shift in the form :

$$\Delta I(\nu_0)d\nu_0 dt_0 = \{B(\nu,t)d\nu dt d\omega \;\Delta A\}/(1 + \delta) \qquad (4)$$

where δ is the red shift of the source and :

$$\frac{\nu}{\nu_0} = \frac{d\nu}{d\nu_0} = \frac{R(t_0)}{R(t)} = \frac{dt_0}{dt} = 1 + \delta \qquad (5)$$

Furthermore[3] :

$$\Delta A = \frac{R^2(t)r^2 \;\Delta\Omega}{(1 + kr^2/4)^2} \qquad (6)$$

where $\Delta\Omega$ is the solid angle subtended by the area ΔA at the observer. Whence, by (3)–(6) :

$$\Delta I(\nu_0) = \frac{B(\nu,t)\;\Delta\Omega}{(1 + \delta)^3} \qquad (7)$$

and so the required surface brightness function is :

$$B(\nu,t) = \frac{\Delta I(\nu_0)}{\Delta\Omega} \cdot (1 + \delta)^3 \qquad (8)$$

We note that this formula applies to either an evolutionary model or a steady-state model. In the steady-state case $B(\nu,t)$ would be statistically independent of t, unless a selective bias depending on distance were operating in the observations.

On the other hand, the formula that appears to be generally adopted by radio astronomers has been given[5,6,3], and evidently followed in the published calculations even for very distant sources, as :

$$B(\nu_e) = \Delta I(\nu_0)/\Delta\Omega \tag{9}$$

Since this formula is valid only for a Newtonian and non-expanding universe it may lead to serious error when applied to distant sources in the actual universe. For example, in the steady-state universe the received intensity $\Delta I(\nu_0)$ at a given frequency ν_0 must tend to zero when the source approaches the observational horizon of the model ($\delta \to \infty$). But, as I have remarked earlier, $\Delta\Omega$ tends to a non-zero limit for a given ΔA. Consequently, if in such a universe B were calculated by (9), instead of (8), it would be found to tend to zero. This is evidently a contradiction of the postulated steady state.

Another important point to notice is that $B(\nu,t)$ is calculable in this way for the emission frequency only, and in general at the epoch of emission only. Given $B(\nu,t)$, the local surface temperature would be calculable from the Rayleigh–Jeans law in the usual way, for the frequency ν and epoch t.

I have applied the formula (8) to calculate the surface brightness of the recently identified source I.A.U. 14*N*5*A*, the red shift[7,10] of which is 0·461 and the half-power diameter[1] is 4½″. Adopting a half-power apparent intensity of 37×10^{-26} W.m.$^{-2}$ (c./s.)$^{-1}$ at 159 Mc./s. for this source one finds an average temperature at the emission frequency of 232 Mc./s. equal to $1{\cdot}86 \times 10^{8}$ deg. K. On the other hand, the Cygnus *A* source, assuming it has a principal area of radiation of $2 \times 50'' \times 30''$ as given by Jennison and Das Gupta[8], has an average surface temperature of 7×10^{7} deg. K. at 232 Mc./s. Consequently, the 14*N*5*A* source was more than 2½ times as bright as Cygnus *A* at this frequency at their respective epochs of emission. This ratio would evidently hold over the wide range of frequencies for which the spectral indices of these two sources are nearly equal[9]. The ratio may even be as much as twice this value since we have not allowed for possible separation of components in 14*N*5*A* as we have done for the Cygnus *A* source.

It is indicated that the luminosity distribution of radio sources may be wider than has been anticipated. On the other hand, if it were found that the average brightness of the sources increased systematically with distance, assuming there was no selection effect, then this would be evidence of an evolutionary universe.

The Interpretation of Cosmology

WE are submitting herewith some further reflexions on the communication by Prof. W. H. McCrea[1], which dealt with uncertainty in cosmology.

(1) The inaccuracy of observations necessarily increases with distance. However, it cannot be excluded *a priori* that in the future the observational error concerning any chosen distant part of space could be brought below any pre-determined limit.

(2) The present cosmological theories imply a fairly large number of definite statements on future observations. This is implicitly admitted by McCrea, who points out with considerable generality that they differ from each other by $(1 + z)$, that is, by a well-determined factor[2] (z is the red shift).

It obviously follows from the above that it is a mistake to exclude the possibility of discrimination between the existing theories. (Discrimination does not mean, of course, verification.)

(3) According to McCrea, predictions relating to the immediate future of remote points of the "world picture"[3] imply an unavoidable uncertainty increasing with $(1 + z)$, that is, with the same factor by which the predictions of the existing theories differ from each other. From this he infers that the theories mentioned above cannot be distinguished from each other.

We wish to point out that in (1) the word 'prediction' is used in two different senses :

(*a*) Prediction for the immediate future of points of the world picture.

(*b*) Prediction of the results of measurements not yet carried out but considered as being realizable at an epoch, contemporary in a cosmological sense.

It is known only in theories based on an adequate cosmological principle that the two concepts are connected : in the case of these theories the immediate future of a point is definite (it is identical to the presence of a well-determined neighbouring point in the world picture). It seems to us that to go over from one meaning to the other within one and the same train of ideas may at best be justified by accepting the definite immediate future.

After these preliminaries let us examine one of the most important inferences of Prof. McCrea's communication, according to which it is in principle impossible to make a distinction between the two basic types of cosmological models. As mentioned above, if we accept our reflexion (1), we cannot deny the possibility of making a decision between the current theories. Therefore the only way to repudiate this possibility is to disprove (1) ; that is to say, to prove an irreducible uncertainty in observation. Instead of this, McCrea asserts that an irreducible uncertainty subsists as regards predictions. This, in his opinion, would characterize theories which are correct in the sense of not supposing homogeneity. It is evident that this can by no means serve as a basis for inferences regarding the distinction between existing homogeneous models. Not only is the logically relevant premise substituted by an inadequate one, but also in the same syllogism no distinction is made between the two kinds of predictions and thus McCrea's wording involves the negation of his own premise, that is, the assumption of the definite immediate future. The inaccuracy of the conclusion can be sufficiently proved by a single example : although the predictions of the Einstein universe differ from the evolutionary models only by a similar function of some distance parameter yet observations have disproved them, beyond any doubt.

These objections in themselves do not affect McCrea's main idea, according to which, independently of the degree of theoretical development and instrumental improvement, full information on the effects influencing some remote part of the universe may be obtained only by observations continued throughout an objectively determined and cosmologically considerable period of time. McCrea infers from this that only theories embracing finite parts of space-time may be considered as realistic.

In our opinion the most valuable idea in McCrea's communication is the delimitation of what in principle is obtainable by a newly developed investigation programme. Its main deficiency is that he wants to insert the uncertainty, discovered in his own "cosmology", into the framework of well-defined theories of present cosmologies.

Neither can we accept McCrea's scientific-philosophical point of view, as we do not consider the cosmological investigations built up on working hypotheses which cannot be established directly to be superfluous. The possibility of model examinations might be understood from the following: in the first place, Nature is entitled to reject scientific prejudices (speculative considerations which are essentially subjective must be pushed into the background). Here, as in all other scientific examinations, we have to take it for granted that any inaccurate statement concerning Nature must, sooner or later, clash with an observational fact. Consequently, every logical theory built on scientific basis is justifiable, provided it is "vulnerable"[4], for example, in its predictions, so that there is the possibility for Nature to prove that it is wrong. No examples are needed to demonstrate the tremendous progress which could be made in science, through the discussion of some theories which seem, for the moment, to be controllable only in indirect ways, even if their formal aim is the examination of the universe as a whole, and the decision as to their scope is postponed for the future. Therefore we consider model investigations as one of the possible theoretical methods of cosmological examination available at the present.

ASTROPHYSICS

Solar Wind and the Gegenschein

To account for the motion of comet tails, Biermann[1] has suggested that there is neutral ionized hydrogen streaming outward from the Sun, and that at the Earth's orbit this plasma has a density typically of the order of 10^2 protons cm.$^{-3}$ and a velocity of approximately 500 km. sec.$^{-1}$. During periods of violent solar activity the velocity increases possibly to 1,500 km. sec.$^{-1}$ and the density increases by one or two orders of magnitude. Parker[2] has also shown that for theoretical reasons there is a hydrodynamic expansion of the solar corona, referred to as the 'solar wind', and that at the Earth's orbit the solar wind has approximately the same density and velocity as estimated by Biermann.

The interaction of a solar corpuscular emanation with the geomagnetic field is exceedingly complex, and for many years it has been invoked as the basic mechanism for explaining a wide variety of geomagnetic, auroral, and upper atmospheric phenomena. Yet apart from the deflexion of comet tails there is singularly little direct observational evidence in support of the solar-wind hypothesis. The purpose of this communication is to direct attention to some additional observational evidence which supports the idea that there is an interplanetary plasma streaming away from the Sun with a velocity close to that estimated by Biermann and Parker.

Since the pioneer work of Chapman and Ferraro[3], it has been agreed generally that the effect of a solar wind impacting against the geomagnetic dipole field is to compress the field into a radius, variously estimated by different authors, of 5–15 Earth radii on the Sun's side of the Earth. Until recently, there was rather less agreement on the subject of what happens to the geomagnetic field on the night-side of the Earth. It now seems with reasonable certainty that some of the magnetic flux from the polar regions, above the auroral latitudes, is carried round to the night-side and the flux-lines are stretched away from the Earth by the solar wind[4]; this 'arch' of polar magnetic flux does not rotate with the Earth or with the magnetic field at lower latitudes. Some of the flux-lines originating from the geomagnetic polar regions are entangled and embedded in the solar wind[5], and are carried away[6] as a "wind carries smoke from a chimney stack", and thus form[7] a 'magnetic tail' to the Earth. Piddington[7] has also made the interesting suggestion that the gegenschein is located within the Earth's magnetic tail.

The gegenschein, or counterglow, is a faint patch of light in the night sky close to the ecliptic and directly opposite the Sun. Visual[8,9], photometric[9–11] and spectroscopic[9,12] observations by the Russian workers Astapovitch, Divari, Fesenkov, Karimov and Rozhkovski have established that the gegenschein glow is elliptical in shape and has a size roughly of 10° by 6°, with the major axis lying nearly along the ecliptic; that it has short- and long-term fluctuations in size and brightness which apparently have some correlation with solar, auroral and airglow activity; that its position as determined by parallax measurements is variable and is at a mean distance of 20 Earth radii; that its emission spectrum in the visible range consists principally of lines common to the night airglow; and that it has a small but variable displacement to the west of the midnight meridian amounting to a mean value of 3°. Roach and Rees[13] have made photometric studies, and conclude that the gegenschein and the adjacent zodiacal light are due to separate and distinct concentrations of particles. It thus appears that the known properties of the gegenschein are consistent with the idea of a slightly luminous magnetic tail to the Earth, and that the magnetic tail is in fact also the gaseous tail proposed by Arrhenius, Houzeau[14] in 1888, and later discussed by Evershed[15] in 1902. The luminosity is presumably owing to the presence of atmospheric-type atoms which, initially, have migrated along the polar flux-lines as ions and become enmeshed in the magnetic tail.

Since the Earth has an orbital velocity of $v_e = 30$ km. sec.$^{-1}$, it is immediately obvious that a solar wind of velocity v_r streaming radially away from the Sun will form a magnetic tail which is directed to the west of the midnight meridian, and if the angular displacement is α, then:

$$v_r = v_e \cot \alpha \qquad (1)$$

Using the observed value of $\alpha = 3°$ it follows that the solar wind has a mean velocity of 600 km. sec.$^{-1}$. This velocity is remarkably close to the value estimated by Biermann and Parker.

On looking for alternative possible causes of the gegenschein displacement one notices that if neutral atmospheric molecules are ejected, by some unknown means, from the Earth at a velocity v in a direction away from the Sun, the conservation of angular momentum gives a westward displacement of:

$$\alpha = v_e r / vR \qquad (2)$$

for $r \ll R$, where R is the radius of the Earth's orbit and r is the distance of the molecules. For r equal to 20 Earth radii, and v equal to 1 km. sec.$^{-1}$ corresponding roughly to the mean speed at a temperature of 10^3 °K., one finds that α is 3° as required. However, it would seem that the main weaknesses with this explanation are: first, that α is proportional to r, and therefore a gaseous tail observed from the Earth would tend to spread westward in a noticeably asymmetric way; secondly, that a large distribution in the values of v would mar the possibility of a definite and confined region of luminosity; and thirdly, it encounters the hitherto unsolved problem of the gaseous tail theories of accounting for a practically non-divergent jet of gas[16].

In all probability the solar wind at the Earth's orbit is not directed entirely radially from the Sun, and therefore equation (1) must be modified to:

$$v_r = (v_e - v_\perp) \cot \alpha \qquad (3)$$

where $v_\perp$ is the transverse velocity of the solar wind at the Earth's orbit in the direction of the Earth's orbital motion. If the angular momentum of the solar wind is conserved from the inner corona, the transverse velocity at the Earth is 0·01 km. sec.$^{-1}$ and is too small to affect noticeably the position of the gegenschein. But if the solar wind and the Sun are electromagnetically coupled[17] and tend to rotate together, the maximum possible distance from the Sun for co-rotation is 0·17 of the radius of the Earth's orbit, and corresponds to the Kepler orbit in which the angular velocity is that of the Sun. In this case the transverse velocity at the Earth is 12 km. sec.$^{-1}$, and according to equation (3) the solar wind has therefore a radial velocity of 360 km. sec.$^{-1}$ for a displacement of 3°.

It must be admitted that our present knowledge of the gegenschein is inadequate and is far from being in a satisfactory state. The little that is known, however, is not inconsistent with the idea of a solar wind interacting with the geomagnetic field and producing a slightly luminous gas-magnetic tail to the Earth. Therefore, if it is accepted that (1) the solar wind carries away a magnetic tail from the Earth, and that (2) the gegenschein is a luminosity associated with the magnetic tail, then the characteristic westward displacement of 3° confirms that the solar wind has a mean velocity close to 500 km. sec.$^{-1}$.

Existence of Net Electric Charges on Stars

PROF. V. A. BAILEY has recently proposed[1] an equation relating the electric charge on a star to the Newtonian gravitational constant and to the mass of the star. This equation has the form:

$$Q = \beta G^{1/2} M \qquad (1)$$

where Q is the electrostatic charge, β is a dimensionless constant of approximately 0·03 for the Sun, G is the gravitational constant, and M is the mass of the star. For the Sun, Q turns out to be $1{\cdot}5 \times 10^{28}$ e.s.u. I wish to point out that equation (1) is closely related to a similar equation which I have obtained for the gravitational fields in the interior of fundamental particles (electrons and protons) by applying the Weyl theory of gauge invariance to the Einstein–Ricci curvature tensor.

Since in the original Weyl theory the dimensions of a charged particle change as it moves from point to point in an electromagnetic field, it is necessary to alter this theory by imposing two constraints if it is to lead to results with physical meaning[2]. The first of these constraints limits the motion of the particle to that path between any two points along which the total change in the dimensions of the particle is a minimum. This at once leads to the Lorentz pondermotive force. The second constraint limits the possible paths still further by requiring that the dimensions of the particle take on their initial values when the particle returns to its starting point. This gives us the Bohr–Sommerfeld quantum condition.

If one[3] now enlarges the Einstein–Ricci curvature tensor by imposing the condition that it be gauge invariant, the additional terms that are obtained are related to the electromagnetic 4-vector and Maxwellian field. If an invariant is constructed with this enlarged tensor, and this is then taken as the Lagrangian density, one obtains the second-order Dirac equation as written down by Feynman and Gell-Mann[4] provided the radius of Gaussian curvature in the neighbourhood of the electron is placed equal to the Compton wave-length $\hbar/mc$.

Since the formula for the Gaussian curvature contains the gravitational constant G as a factor, one is thus led to the following equation for G inside an electron (or proton):

$$G = \hbar c/m^2 = \alpha^{-1}(e/m)^2 \tag{2}$$

where α is the fine structure constant, $e^2/\hbar c$, and e is the electronic charge. Thus the value of the gravitational constant inside an electron is of the order of 10^{34} C.G.S. units.

If we take the square root of (2) we obtain Bailey's equation for the Sun:

$$G^{1/2} = \alpha^{-1/2}(e/m) \tag{3}$$

provided we identify his constant β with the square root of the fine structure constant, $e/(\hbar c)^{1/2}$. Of course, the two quantities are numerically different, but that is simply because the quantity that we must use in place of $e/(\ c)^{1/2}$ if we wish to apply (3) to the Sun is:

$$\beta = Q/(2I\omega c)^{1/2} \tag{4}$$

where I is the moment of inertia of the Sun, ω is its angular velocity, and c is the speed of light.

In other words, what is significant in formula (3) is not the appearance of Planck's constant but rather the appearance of an angular momentum. If we are to apply (3) to the Sun, we must introduce a kind of 'fine structure constant' corresponding to the angular momentum and charge of the Sun.

If in (4) we introduce Bailey's value for Q and use the value of I obtained from calculations of radius of gyration for solar models[5], the value of β is about 0·03 as postulated by Bailey.

What is perhaps more interesting is that (2) leads to the expression relating the mass and the radius of a finite universe as first derived by Einstein in 1916. If we consider the universe as a closed system with intrinsic angular momentum $I\omega$, then the radius R of the universe must be such that $R\omega = c$ or $\omega = c/R$. If we now take I to be kMR^2, where k is a numerical factor approximately unity, then the expression for G for the universe as a whole becomes:

$$G \simeq I\omega c M^{-2} = kRc^2M^{-1} \tag{5}$$

This is just Einstein's formula for a universe of radius R and mass M. It is interesting to note that an equation of the form (2) has been suggested by Chandrasekhar[6] as the most general combination of the constants $\hbar$, c and G, and the mass of the proton.

PROF. MOTZ'S model of an electrically charged fundamental particle is of particular interest because it directly contradicts the commonly held view that gravitational fields on the atomic scale are quite negligible. By means of some bold but simple hypotheses he appears to obtain a model of an electron (or proton) which is capable of holding its parts together against the electric forces of repulsion between these parts.

Prof. Motz's comparison of his equation (2) with my equation (1) is also of interest, because it extends the similarity between astronomical systems and atomic systems which was first demonstrated by Bohr and Sommerfeld's theories and their extension by Goudsmit and Uhlenbeck; but here the similarity is one between single constituents of these two kinds of systems.

It is remarkable that the order of magnitude, 0·03 for the pure number β in the equation (1) is consistent with the values derived by Motz from his table of solar models published in his ref. 5. It should, however, be noted here that on reconsideration of the data on which I based my first estimate of β, I have recently reduced its value to about 0·006 and correspondingly reduced the Sun's charge to about -3×10^{27} e.s.u. But the uncertainties in the data make even this recent estimate merely one of order of magnitude.

In a recent communication[1] on the apparent steady component of the interplanetary magnetic field, it is shown that the findings of the magnetometer on the space probe *Pioneer V* during the first 50 days of operation strongly support the hypothesis that the Sun carries a large negative charge. But from that communication it may be inferred that in order to determine the value of β experimentally in this way it would be necessary to make measurements by means of instruments carried in space probes moving in different orbits. Such a determination of β is highly desirable, since it would be not only of interest to astronomers but also might be of value in connexion with Prof. Motz's considerations.

PHYSICS

Effect of Dissolved Air on the Viscosity of Water

WATER at 20° C. is now widely used as the primary standard for viscosity measurement[1], the viscosity being taken to be 0·01002 poise as obtained by Swindells, Coe and Godfrey[2], and confirmed by Roscoe and Bainbridge[3]. The International Organization for Standardization has recently proposed the international adoption of this value, but the question has arisen whether the viscosity depends significantly on the presence of dissolved air in the water[4]. We have now made some very accurate measurements to determine the effect of dissolved air, and found it to be insignificant for present standards requirements.

The viscosity of air-saturated water has been measured relative to that of air-free water. The measurements were made using sealed suspended-level viscometers incorporating fine platinum contacts by means of which electronic timing equipment is triggered. The viscometers were immersed in a stirred water-bath, the temperature of which was kept constant to within ± 0·0007 deg. C. by a proportioning controller and measured with a platinum resistance thermometer. Within a set, the concordance of flow-times was 1 part in 50,000.

The ratio of the flow-times obtained at 20° C. with and without air at atmospheric pressure in the viscometers was found to be 1·00125 ± 0·00009 at a 95 per cent confidence-level. To obtain the corresponding ratio of kinematic viscosities, this figure must be reduced by 4 parts in 100,000 for the effect of the pressure difference on the dimensions of the viscometers, and by a factor of 1·00119 for the effect of the buoyancy of the water with respect to the water-saturated air. The resulting viscosity ratio does not differ significantly from unity. More specifically, the effect of air at atmospheric pressure on the kinematic viscosity of water does not exceed 13 parts in 100,000 at the 95 per cent confidence-level. This statement relates to the combined effects of the dissolved air and the pressure; but it can be shown independently, by extrapolating data available for higher pressures, that the direct effect of a pressure of one atmosphere is to change the viscosity by no more than a few parts in 100,000.

Likewise, at 25° C. and 30° C. no significant effect was found.

A Phenomenon in *n*-Hexane prior to its Electric Breakdown

A PRELIMINARY photographic study has been made using a schlieren optical system in which a 1-microsecond flash-light source was arranged to flash five times in synchronism with a single-step function voltage applied to electrodes immersed in highly purified *n*-hexane. The events were recorded with a rotating-mirror camera.

In the examples shown in Fig. 1, the first photograph in each series shows the undisturbed state of the liquid prior to the application of the voltage. Each second photograph, taken 7 μsec. after the application of the voltage, shows that the refractive index in a localized region at the pointed cathode has become different from that in the surrounding liquid. The extent of the localized region was observed to be greater with higher voltages under otherwise similar conditions.

The phenomenon at the cathode can disappear (Fig. 1*A*) without breakdown ensuing, even with the voltage maintained. On the other hand, Fig. 1*B* shows a spark breakdown, which is self-luminous and therefore recorded, about 20 μsec. after the application of the voltage. The later photographs record the bubble originating from the spark. Fig. 1*C* shows similar phenomena in a point-plane gap with the breakdown about 10 μsec. after the application of the voltage.

All these phenomena are detectable with a shadowgraph technique, which is less sensitive than the schlieren technique; thus the refractive index of the region at the cathode must be greatly different from that of the surrounding liquid, but it is not known whether it is higher or lower.

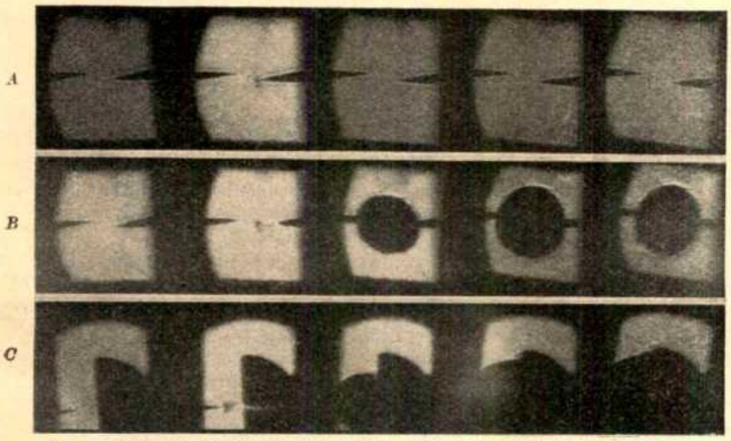

Fig. 1. Synchronized schlieren photographs of pre- and post-breakdown phenomena in *n*-hexane. In each series the first photograph was taken 70 μsec. before the application of a step function voltage, and the remaining photographs were taken, respectively, 7, 80, 150 and 220 μsec. after the application of the voltage. Ratio voltage/gap-length: *A*, 325 kV./cm.; *B*, 335 kV./cm.; *C*, 330 kV./cm.

Emission of Soft Electromagnetic Radiation from Metals by the Impact of High-Energy Protons and Positive Ions

IT is known that the impact of fast protons[1] and α-particles[2] on metals results in the emission of their characteristic X-radiation. It has not been reported, however, whether ultra-violet and visible radiation are also emitted from metals when high-energy protons and positive ions strike them. Sir J. J. Thomson[3] predicted as early as 1914 that the impact of positive ions on metals may result in the emission of soft electromagnetic radiations. Evidence supporting this view has been given in recent experiments, where it is shown that ultra-violet and visible radiation is emitted when positive ions and protons of moderate energies strike a nickel surface[4]. These experiments have now been extended to protons and positive ions of energies of 400–700 keV.

A proton beam was obtained from an Oliphant ion source[5] of our 1·2-MeV. Cockcroft–Walton generator, supplied by Messrs. Philips Electrical Co. of Eindhoven, Holland, and described earlier by one of us[6]. It was analysed with a 15° permanent magnetic analyser using an adjustable magnetic shunt. The voltage for the ion source was obtained from a 0–50-keV. transformer energized by a remote controlled 0–220-V. a.c. generator driven by a large insulating belt, both installed in the top of the accelerator along with the Oliphant discharge tube and the gas reservoir.

The output voltage of the transformer was rectified with a Philips high-tension five-ring mercury rectifier valve and was stabilized with an R.C. filter, and the gas-flow to the ion source was regulated by a remote-controlled needle valve. The discharge was run at 10–20 m.amp. with discharge potential of 20–30 kV. Protons travelled through a long metal tube cooled with liquid air and entered the target chamber through a narrow aperture before striking the target 10 cm. below. The main accelerating column was exhausted with a large diffusion pump backed by a Kinney pump. A separate set of these pumps evacuated the proton-collimating tube and the target chamber through a large liquid-air metal trap continuously during experiments.

Observations were taken with proton current varying from $1 \cdot 0 \times 10^{-7}$ amp. to $4 \cdot 0 \times 10^{-6}$ amp. Radiation emitted from the target was detected with a photoelectron E.M.I. multiplier type 6260 and with associated electronic equipment, and was studied with Kodak gelatine filters supplied by Kodak, Ltd., of London.

It was observed that soft electromagnetic radiation in the visible and ultra-violet regions is emitted from a nickel target, in a well-degassed as well as in an un-degassed condition. The intensity of the radiation in the ultra-violet region above 3300 Å. was greater than that of the visible part of the spectrum in either case. The total intensity of the radiation of wave-length above 3300 Å. rises more rapidly than the increase in the proton current and is always greater from a dirty surface than from a clean one. It shows, however, a decrease of about 20 per cent as the energy of the protons is raised from 400 to 700 keV. at a constant proton current. The spectrum in the visible region was continuous, with a pronounced flat peak between 4600 and 4900 Å. Radiation of wave-length above 5200 Å. was not measured, however, on account of experimental limitations. A spot visible to the naked eye appears on the target with as small a current as $1 \cdot 0 \times 10^{-7}$ amp.

In one set of experiments the target was well degassed under high vacuum by electron bombardment at bright red heat for several hours before observations were taken. The degassed target was left under vacuum overnight and observations were repeated the following day after degassing it again, when the results were found to be reproducible.

Experiments have also been performed with unresolved hydrogen ions obtained from a 30-Mc./sec. radio-frequency source recently installed in our accelerator. Hydrogen flowed from the gas reservoir to the radio-frequency discharge tube through a remote-controlled nickel valve the temperature of which determined the gas-flow and thus the discharge pressure. The voltages for the focusing lens and the ion-extracting probe were obtained from 50-kV. and 5-kV. selenium rectifier Cockcroft–Walton cascade sets, respectively, which were both remote controlled and were placed in the top of the accelerator with the power supplies for the 30-Mc./sec. oscillator. The positive ion current to the target was adjusted by varying the pressure of the discharge gas or the voltage of ion-extracting probe or both and was varied from 4×10^{-6} amp. to $15 \cdot 0 \times 10^{-6}$ amp. while the energy of the ions was kept at about 400 keV. We have observed that the radiation emitted from the nickel target, both from its dirty and clean surfaces, gives a continuous spectrum in the visible region in this case also. The spectral intensity distribution curve is flat from 4000 to 4700 Å., beyond which it falls rapidly. The intensity of the visible radiation with current of 10×10^{-6} amp. and above was too high for direct measurement, and Kodak neutral density filters were used to cut it down for recording with the electronic circuits. In one set of observations the ion current was raised to a value high enough to make the target glow bright red due to bombardment when it was kept under this condition for several minutes for degassing, and was then suddenly decreased to about 4 μamp. for taking observations from a clean surface freshly prepared.

We have checked that the radiation detected by us is not due to the secondary electrons emitted from the edges of the aperture by the protons entering the target chamber, nor is it due to their heating effect on the nickel target. Details of the experiments will be published elsewhere.

We are indebted to Sir John Cockcroft and to Sir Mark Oliphant for advice and encouragement, and to Dr. Paul W. McDaniel, director of the Research Division, U.S. Atomic Energy Commission, for helpful discussion and suggestions. We also thank the U.K. Government for the gift of high-tension selenium rectifiers and the 30 Mc./sec. radio-frequency ion source recently installed in our accelerator under the Colombo Plan.

Flow Patterns in Particle Beds

THE technique of observing gas-flow patterns in fluidized beds described in a recent communication[1] is a useful contribution to the methods available for investigating fluidization behaviour. A comparable technique has been developed here using dye injection for tracing the flow pattern of water passing through particle beds. Though this technique was found useful in the pre-expansion stage, it was the reverse during bed expansion when it actually tended to mask the interesting phenomena shown in Fig. 1. These photographs were taken by transmitted light without the use of dyes, and show the activation of a bed of 100μ glass spheres by water. Local bed expansion or increased voidage is indicated by increase in transmitted light. Photograph *C*13 shows the approximate steady-state conditions in a bed which, viewed superficially, has all the appearance of uniform and smooth particulate fluidization. The series *A*1–*A*12 (of which *A*1, 3, 6 and 12 are reproduced) shows the development of a flow pattern in the same bed at a much lower superficial water velocity. The last of that series again approximates to steady-state conditions, the only changes thereafter being a slow meandering of the flow channels. Not seen in the photographs but observed visually are occasional series of mushroom-shaped low-density discontinuities rising in one or more of the channels.

The visual study of particle bed activation by air was studied here in a parallel-plate apparatus using

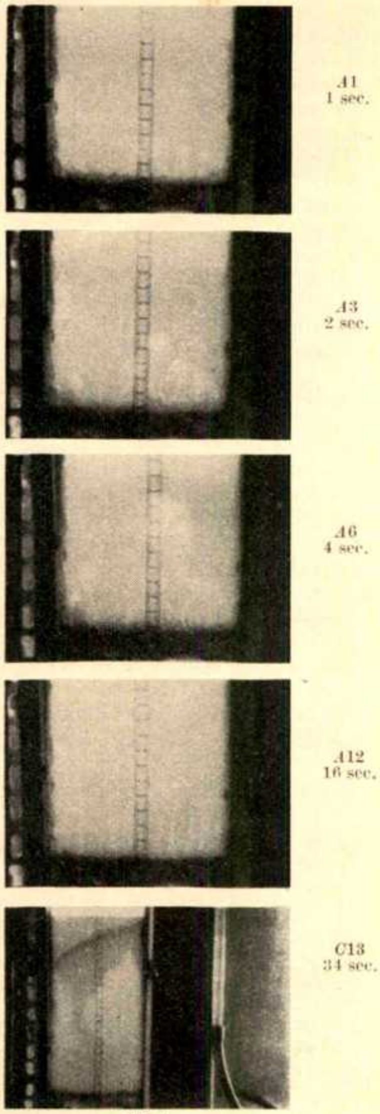

Fig. 1

mixtures of particles with differently coloured size ranges. It was possible to observe the circulation of 300-mesh particles of alumina dyed red, within air bubbles held stationary by stiction effects in a bed of 100 mesh undyed alumina. A modification of this apparatus, suitable for water fluidization, was made with the prime object of investigating what appeared to be anomalous and hitherto unreported behaviour, namely, an apparent bubbling stage in water fluidized beds of small, moderately dense particles. In all cases studied, the expansion from fixed bed to particulate fluidization passed through a stage closely resembling the gentle bubbling stage in air fluidization. Streams of mushroom-shaped pseudo-bubbles can be observed rising in narrow channels within water-activated beds of alumina and glass spheres within the size range of 60–200μ, but it is not clear whether these are of the same nature as bubbles in air-activated beds, or some type of vortex phenomenon. In the case of glass spheres larger than 1 mm. diameter, horizontal striation can be observed with low-density strata being propagated upwards continuously and evanescing at the top of the bed. These occasionally break and re-form, giving an appearance of mushroom-shaped bubbles.

The term 'parvoid' is suggested as a generic term to describe these and other low-density discontinuities in fluid-activated beds. With 2-mm. glass spheres, parvoids of mushroom shape ranging from 1 cm. to 5 cm. in width can be seen rising at some 5 cm. per sec. through the dense bed at superficial water velocities of some 2 cm. per sec. These parvoids give the impression of being completely void of particles, in contrast to parvoids in beds of smaller particles.

The possible existence of discontinuities and non-uniformity in what have hitherto been considered to be homogeneous beds may have some relevance to much published work in the literature. A complete account of these discontinuities with a tentative theory as to their formation and relationship to fluidization behaviour will be published elsewhere. There is evidence that what is known as particulate and aggregative fluidization may be occurring at one and the same time in a fluidized system, and that it is the proportion in which they occur that defines the one type of fluidization as against the other. If this is so, one could expect a transition from one to the other in any fluid-activated particle system, as the fluid velocity is increased in stages.

BIOPHYSICS

Molecular Sieve Behaviour of Dental Enamel

NORMAL mammalian tooth enamel is highly calcified, containing 97 per cent mineral and 3 per cent organic material and water. The mineral is hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, and it is associated with a protein constituent of the keratin type[1]. From histological studies it is well known that normal enamel is made up of structural units which are prismatic in shape and contain mainly crystallites of hydroxyapatite. The organic constituent is concentrated at the margins of these prisms but it is also present in smaller amounts within them. In the prisms the crystallites are highly oriented, with their optic (fibre) axes approximately parallel with the longitudinal axes of the prisms. This submicroscopic structure of normal enamel is shown diagrammatically in Fig. 1. The fully formed enamel can be broken down either *in vitro* by organic acids such as lactic acid, or *in vivo* by the processes concerned in carious decay. In each case the mineral is gradually dissolved out until, eventually, the structure of the enamel is destroyed[2].

Since hydroxyapatite is a uniaxial mineral possessing negative birefringence, normal enamel shows a negative intrinsic birefringence relative to the longitudinal axis of the prism due to this inorganic component. This is the only birefringence shown by normal, fully formed enamel. However, during both formation and acid breakdown of normal enamel, it has been shown that a considerable number of freely accessible spaces exist between the crystallites in the prisms, and these spaces can give rise

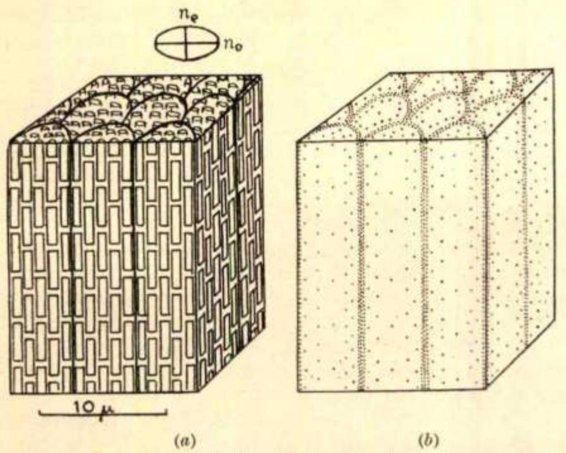

Fig. 1. Diagrams illustrating the fine structure of normal tooth enamel. (a) The arrangement of mineral elements. The enamel consists of columnar prisms within which are tightly packed, rod-shaped crystallites of hydroxyapatite. The index ellipse of the crystallite system is indicated by the axes n_e and n_o. (b) The distribution of organic elements. A keratin-like protein material is concentrated around the margins of the prisms, but smaller amounts occur throughout

to an additional optical effect. A system of rod-shaped elements, such as crystallites, separated from each other by spaces containing a medium of different refractive index, constitutes a 'mixed body'[3]. A rodlet mixed body produces positive form birefringence relative to the direction of orientation of the rods. It follows, therefore, that enamel which is being formed or which is undergoing breakdown will show negative intrinsic birefringence due to its oriented inorganic component and positive form birefringence due to the intercrystallite spaces[4].

The strength of the positive form birefringence depends on the difference between the refractive indices of the crystallite material ($n = 1{\cdot}62$) and that of the medium occupying the spaces between the crystallites. The latter may be altered by the inclusion in these spaces of, for example, air ($n = 1{\cdot}0$), water ($n = 1{\cdot}33$), organic liquids such as alcohols ($n \sim 1{\cdot}4$) or quinoline ($n = 1{\cdot}62$)[2]. Quinoline has the same refractive index as the crystallite material. If it is used as the imbibing medium, form birefringence will not be produced and only the negative intrinsic birefringence of the mineral will be apparent. If the spaces are occupied by a medium of lower refractive index than this, then the result will be a summation of the positive form and the negative intrinsic birefringences. With media of refractive index 1·45, these opposing effects tend to compensate each other so that the system shows no activity between crossed polars. With media of lower refractive indices than this, the positive form birefringence predominates.

Using this method it has been possible to examine the nature of the spaces present in certain parts of the carious lesion (Fig. 2), and it has been found that the body of the lesion, which develops at a relatively late stage in the attack, behaves in exactly the way described[2]. However, one of the earliest stages of the carious lesion is the appearance of an opaque zone when examined in Canada balsam. This is the so-called dark zone. The development we wish to report concerns the detailed structure of the dark zone and the determination of the relative sizes of the spaces which are present, by showing that the extent of inclusion of organic liquids into these spaces depends on their molecular dimensions. It should, perhaps, be pointed out that whatever the size of spaces in the dark zone, the total volume of spaces is very small[5].

The dark zone is observed only in certain circumstances, for example when a tooth section is examined in media such as Canada balsam or quinoline (Fig. 2). It is also seen when a section is examined in air, but is not easily distinguished because it is concealed by the form birefringence of the neighbouring parts of the lesion. The dark colour of the zone as seen in transmitted light, as well as the strong positive birefringence seen between crossed polars, must be due to the fact that the intercrystallite spaces contain air. This suggests that the occurrence of the zone in sections mounted in Canada balsam or in quinoline is because the molecules of these liquids are too large to be included in the spaces.

This hypothesis has been subjected to experimental scrutiny by examining the optical behaviour of sections of carious lesions in enamel which were first dried and then allowed to imbibe, in turn, the liquids listed in Table 1. The results of a typical experiment are recorded there.

It will be noticed that the degree of observed birefringence becomes progressively more positive as the series of normal (straight-chain) alcohols is ascended from methyl alcohol to *n*-octyl alcohol. This effect cannot be due to differences in the refractive indices of the alcohols since the refractive index is approximately the same in each case. In fact the refractive indices do show a slight increase as the series is ascended. If the changes in refractive index had been influencing the total birefringence, then this would have produced a trend opposite to that observed. It therefore follows that this change in positive birefringence in the series, methyl

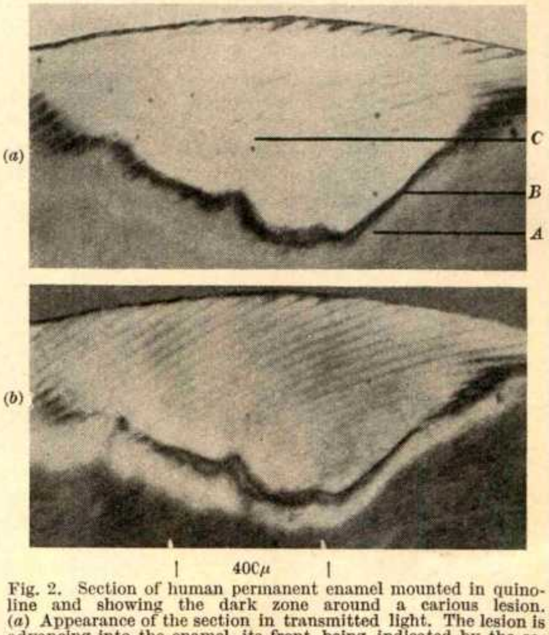

Fig. 2. Section of human permanent enamel mounted in quinoline and showing the dark zone around a carious lesion. (a) Appearance of the section in transmitted light. The lesion is advancing into the enamel, its front being indicated by the so-called translucent zone (*A*). Within the translucent zone is the deep brown, opaque 'dark zone' (*B*), and within this again is the body of the lesion (*C*). (b) Appearance of the same area of enamel between crossed polars. The dark zone shows up as a narrow band with positive birefringence and is delineated on either side from neighbouring areas by black lines of compensation. The rest of the enamel has negative birefringence

Table 1

Water	1·33	− 13·01
Quinoline	1·62	+ 13·21

→*n*-octyl alcohol, is due to changes in the extent of replacement of air ($n = 1{\cdot}0$) by alcohols ($n \sim 1{\cdot}4$) in the intercrystallite spaces. As the homologous series is ascended, the molecular size of the alcohols increases. It is suggested that, with any particular alcohol, spaces larger than a certain critical size can be occupied by the alcohol, whereas spaces smaller than this size cannot be occupied and will still contain air. In all the many specimens examined to date, a dark zone has never been observed in methyl alcohol. It may therefore be concluded that the smallest size of intercrystallite space so far detected is such as to allow the inclusion of molecules of methyl alcohol.

It has also been shown (Table 1) that branched-chain alcohols (for example, *iso*propyl or *tert.*-butyl alcohols) are included to different extents from the corresponding normal alcohols. This suggests that the ease of penetration depends not only on the linear dimensions but also on the cross-sectional areas of the intercrystallite spaces.

It should be emphasized that there is a variation in the sizes of the intercrystallite spaces so that with the higher alcohols only large spaces can be occupied, whereas with alcohols of smaller size, a greater number of spaces can be occupied. The extent of inclusion of the various liquids is an interesting demonstration of a molecular sieve phenomenon[6] in a biological system. Similar behaviour has also been observed in the non-carious tooth enamel of a variety of vertebrate animals. In each case the tissue showing the phenomenon appears to contain slightly less mineral than the fully formed normal enamel.

The significance of these results in relation to the understanding of the processes of carious breakdown will be discussed elsewhere[7].

This work was carried out while two of us (K. V. M. and D. F. G. P.) were in receipt of grants from the Medical Research Council, to which thanks are offered.

Thread-like Reticulum in Latex from *Hevea brasiliensis* and its Relation to Latex Particles

IN a previous communication[1] I directed attention to the complexity of the 'lutoids' separated from fresh latex by high-speed centrifuging. I have now made further studies of fresh latex using phase microscopy. As reported in the literature[2-4], aggregates of lutoids occur in untreated fresh latex; I now find these aggregates not only contain lutoids, but also Frey Wyssling[5] particles and pear-shaped rubber particles, all of which occur in a gelatinous matrix. Associated with this gelatinous material, I have observed many very fine threads which often trail from the edges of the aggregates. These are quite distinct from the chains of coagulated rubber which have been reported in latex under certain conditions. Since the particles differ in density, the effect of high-speed centrifuging on the aggregates will be disruptive.

Latex was collected into chilled glass vessels and centrifuged under refrigerated conditions into zones by a technique essentially similar to that of Moir[6]. Moir remarks that the (middle) serum fraction often has a 'ropey' appearance to the naked eye. I now find this is due to many long thread-like processes beaded with particles including lutoids, Frey Wyssling particles, a few rubber particles and many particles too small to be identified. The Frey Wyssling particles commonly occur in grape-like clusters. In positions corresponding to Moir's zone 2 and zone 11 are found patches of translucent jelly. The zone 11 jelly at the bottom of the tube contains many particles, especially lutoids, and sometimes portions of plant tissue. The zone 2 jelly in the upper half of the tube contains threads to which many rubber particles are attached. The general appearance is that of fruit growing from a branch. Pear-shaped rubber particles are attached by their stalk-like narrow ends. Apparently the aggregates seen in untreated latex have been torn apart, rubber particles moving upwards and lutoids downwards, with attached threads and jelly parted between them. A portion remains incompletely separated, intermediate in density, and is found in the serum. Frey Wyssling particles are found in all three regions.

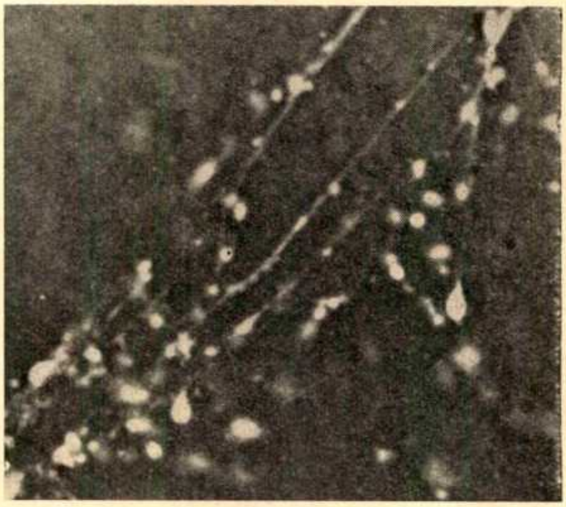

Fig. 1. Rubber particles attached to threads in upper (zone 2) fraction. Lutoids and Frey Wyssling particles have been stripped from the threads by the centrifuging. Reichert negative phase, flash illumination. (× *c.* 2,530)

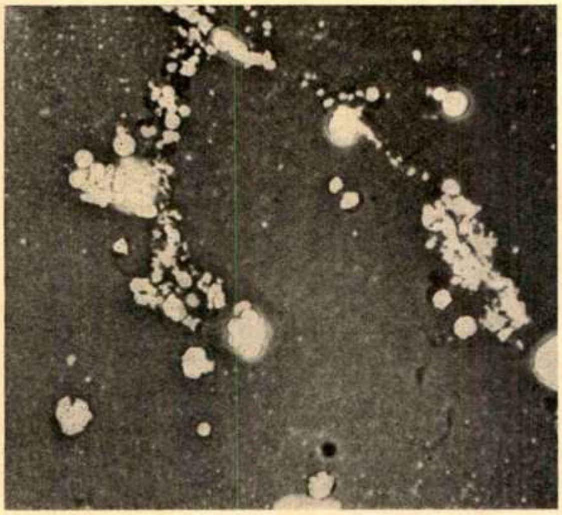

Fig. 2. Partially disrupted aggregates in the middle (zone 5/6) fraction. Rubber, lutoids, clusters of Frey Wyssling particles are still attached. Reichert negative phase, flash illumination. (× c. 1,330)

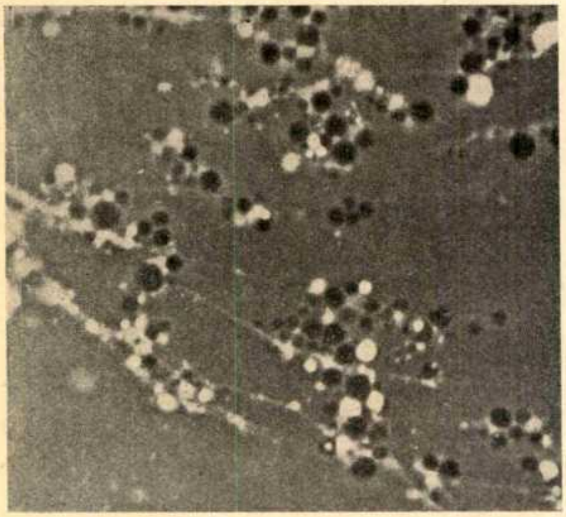

Fig. 3. Lutoids attached to threads in lower fraction from re-centrifuged aggregates. Rubber and most Frey Wyssling particles have been stripped from the threads by the centrifuging. Reichert negative phase, flash illumination. (× c. 1,330)

As supposed by Moir[6], zone 8 is predominantly lutoids. Careful examination shows that some of these have short lengths of thread attached, suggesting that they have been torn from the main thread system. By re-centrifuging serum containing partially separated aggregates, I have been able to concentrate such lutoids. Using time-lapse photography I have recorded interactions between thread and lutoid. Over a period of 2 hr. the thread thickens and proves to be tubular, for the spherical lutoid suddenly discharges its contents into the swollen thread, the whole forming an elongated body enclosing captive particles in motion. A similar experiment with a short length of thread studded with very small particles recorded a swelling which formed locally. The small particles were then seen to be freely in motion within the swelling, so that they must have been contained originally inside the tubular thread and not attached to its exterior. The swollen thread had the appearance of a lutoid complete with captive particles.

From these experiments it seems that the aggregates include all three types of particle commonly seen in latex, linked by a reticulum of fine threads now shown to be tubular and sometimes to enclose very small particles in their interior. The whole constitutes a rather jelly-like matrix and is probably a fragment of a more extensive cytoplasmic structure in the latex vessels, carried away by the outflow of latex. Such a reticulum is, of course, a most likely site for particle synthesis. Normal tapping methods must tear many particles free from their attachments even if they are not liberated by other means. Frey Wyssling's observation[5], that the particles called after him often occur in clusters, is confirmed. It now seems that they are formed in this fashion on the reticulum. Similarly the characteristic pear shape of many rubber particles[7,8] follows from their mode of formation, whether or not the aggregation mechanism proposed by Lucas[9] operates afterwards.

CHEMISTRY

'Ligand Exchange': a Novel Separation Technique

A novel technique for analytical and preparative separations of compounds which can form complexes or adducts with metal ions has been worked out in this laboratory. The new technique can appropriately be called 'ligand exchange'. The method combines two fields of chemistry, namely, ion exchange and co-ordination chemistry, in order to accomplish a task that neither could do alone.

An ion exchanger containing a complexing metal ion (Cu^{2+}, Cu^{+}, Ni^{2+}, Ag^{+}, Co^{3+}, etc.) is used as a solid sorbent. The potential ligands are sorbed from solutions or gases and form complexes with the metal in the resin or displace other ligands which have previously complexed the metal. The latter remains in the ion exchanger. In contrast to conventional ion exchange where counter ions are exchanged, ligand exchange is exchange of ligands for others or for solvent molecules in the ionic solvation shells. Ligands which can be isolated or separated include ammonia, organic amines, polyhydric alcohols, olefins, acetylene derivatives, etc., and anions of organic acids and amino-acids. Separations are preferably carried out in a chromatographic column as in ion exchange chromatography or gas-liquid chromatography. Standard chromatographic techniques—elution development, gradient elution, displacement development, frontal analysis, etc.—can be adapted to ligand exchange.

Ligand exchange has several advantages over other, more conventional chromatographic techniques. First, complex formation is a very strong interaction if the proper metal ion is chosen. This provides a very strong 'driving force' for ligand sorption. Thus, ligand exchangers sorb ligands selectively, utilizing almost their full capacity even when the ligand concentration in the external solution or gas phase is extremely low. In this way, ligands can be very efficiently separated from non-ligands. For example, from 10 litres of a 10-p.p.m. solution of most aliphatic amines, essentially all is sorbed by 1 gm. or less of a cation exchanger in Cu^{2+} or Ni^{2+} form. Secondly, complex formation is a highly specific interaction, much more so than ordinary physical adsorption or ion exchange. Complexes of a metal ion with various, even rather similar, ligands differ greatly in their strength. Hence the ligand exchanger can distinguish rather sharply between such ligands, and outstandingly sharp resolutions in separations of ligands from one another can be obtained even in cases in which conventional sorbents fail. A striking illustration of the specificity of complex formation is the separation of the rare earths by ion exchange chromatography; here, differences in complex-strengths with an eluting or developing agent are used for separating metals. Ligand exchange is a reversal of this technique; differences in complex-strengths with a metal are used for separating complexing agents. For example, with ammonia and an organic diamine, separation factors well above 100 were easily attained. Thirdly, ligand exchange is very flexible since the metal ion giving the best separation can be chosen from a great number of elements.

A unique and particularly useful feature of ligand exchange is the following. In separations of ligands of different co-ordinative valences the selectivity can be adjusted and even reversed at will, simply by varying the total ligand concentration in the external solution or gas phase. Consider, for example, the 'ligand exchange' of a monodentate ligand A (occupying one co-ordinative valence of the metal) for a bidentate ligand B (occupying two co-ordinative valences) with, say, Ni^{2+} as the complexing metal ion:

$$\mathrm{Ni}A_6 + 3B \rightleftharpoons \mathrm{Ni}B_3 + 6A \qquad (1)$$

The mass action law for this exchange can be written as:

$$\frac{[\mathrm{Ni}B_3][A]^6}{[\mathrm{Ni}A_6][B]^3} = K_a = \text{const.} \qquad (2)$$

or

$$\frac{[\mathrm{Ni}B_3][A]^3}{[\mathrm{Ni}A_6]} = K\left(\frac{[B]}{[A]}\right)^3 \qquad (3)$$

For a given constant concentration ratio of B to A, the right-hand side of equation (3) remains constant. Thus, high total ligand concentration (high value of $[A]$ on the left-hand side) favours the complex $\mathrm{Ni}A_6$, and low total ligand concentration (low value of $[A]$) favours the complex $\mathrm{Ni}B_3$. By selecting a suitable metal ion one can adjust conditions in such a way that the monodentate ligand is preferentially sorbed from concentrated solutions and the bidentate one from dilute solutions. For example, a bidentate diamine is economically separated from (monodentate) ammonia by selective sorption of the diamine from a dilute mixture by a cation exchanger in metal–ammonia–complex form. The diamine is then recovered from the column by displacement with concentrated ammonia, which yields the diamine in high concentration. No regeneration is required since, after displacement, the resin is again in metal–ammonia–complex form.

Displacement of the complexing metal ion from the resin by ion exchange with other cations in the external solution interferes with ligand exchange. Such ion exchange can be suppressed by choosing a resin with ionogenic groups which hold the metal firmly by partial complexing. In non-ionic ligand exchange, carboxylic acid groups usually offer sufficient protection. If requirements are more stringent, as is the case in anionic ligand exchange, chelating resins such as 'Dowex A-1' (iminodiacetic acid groups) can be used. A possible alternative is the use of an anion exchanger with amino groups. Of course, such protection against ion exchange is achieved at a sacrifice in ligand exchange capacity since the ionogenic groups block co-ordinative valences of the metal ion. For example, with Ni^{2+}, two co-ordinative valences out of six are blocked in resins with carboxylic acid groups, and three in resins with iminodiacetic acid groups.

Ligand sorption by cation exchangers containing complexing metal ions was observed as early as 1954 by Walton[1]. Separations by virtue of differences in complexing strength have occasionally been achieved by other authors[2]. However, it appears that so far the general applicability of the principle, the inherent advantages, and, in particular, the effect of the co-ordinative valences of the ligands have not been recognized.

Separation factors and column performance in ligand exchange operations can be predicted with reasonable accuracy solely on the basis of the tabulated values of the complex-formation constants. Publication of a theoretical treatment and experimental results is anticipated elsewhere.

Method for studying Thermal Stability of Bulk Thermosetting Polymers

THE use of thermosetting polymers in high-temperature applications is increasing rapidly; but data on the thermal stability and degradation characteristics of these materials are very limited. A few investigations employing differential thermal analysis and thermogravimetric analysis have been reported, but the number of polymers investigated is small. Both methods, while very useful in elucidating the kinetics of the degradation process, require a specially prepared sample and are not suited to yield information on bulk polymers. A new experimental technique, termed electro-thermal analysis, for determining thermal stability of bulk thermosetting polymers, will be described briefly.

Previous work with electrical volume-resistivity measurements[1,2] has shown their usefulness in studying reactions and transitions of cross-linked polymers. It has also been shown[2] that a completely polymerized

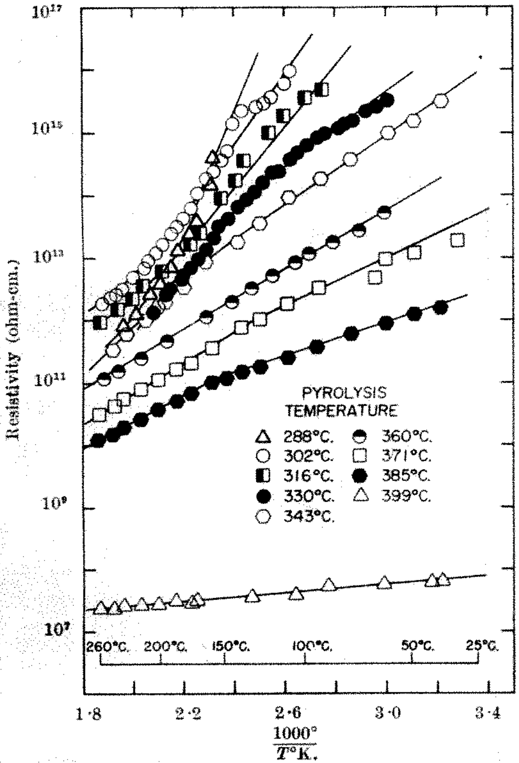

Fig. 1. Temperature-dependence of the electrical resistivity of a thermosetting polymer after pyrolysis for 16 hr. at various temperatures

polymer will exhibit not only the maximum magnitude of resistivity but also the maximum temperature-dependence of resistivity. A cross-linked organic polymer will on pyrolysis exhibit a progressive decrease in these parameters due to degradation, the magnitude of the decrease being approximately proportional to the extent of degradation. At 25° C. the magnitude of the resistivity, $\rho(25°)$, will approach as a limiting value the resistivity of carbon, that is, about 10^5–10^7 ohm-cm., while the temperature-dependence will approach the flat or slightly negative dependence characteristic of carbon. Pyrolysis progressively converts a cross-linked organic polymer into a dense, rigid, extensively conjugated, cross-linked carbonaceous residue[3,4]. This progressive pyrolytic conversion can be measured by resistivity techniques and forms the basis for this investigation. With the exception of a limited study of the structure of several pyrolysates by Winslow and co-workers[3], the use of resistivity measurements in this manner has not been previously reported.

Degradation is determined by repeatedly measuring the temperature-dependence of the resistivity over the range 25–300° C. after each pyrolysis cycle. The arbitrarily chosen pyrolysis cycle is 16 hr. and the temperature is increased about 15 deg. C. for each cycle. Dependence on temperature can be conveniently determined by measuring the resistivity as the pyrolysate is slowly cooled. Onset of thermal degradation is shown by a decrease in the previously established maximum magnitude of resistivity and its dependence on temperature. Pyrolysis is then conducted at progressively higher temperatures until the residue exhibits the electrical properties of carbon. Pyrolysis at still higher temperatures results in graphitization of the carbon and in decreased resistivity[4].

Resistivity measurements are made by a continuous-current monitoring device already described[1]. Parallel-plate electrodes are employed which are completely embedded in the polymer, and pyrolysis is thus conducted in the absence of air. The initial temperature of pyrolysis is a function of the polymer under consideration but will usually be greater than 200° C.

Results obtained by this technique on a fluorinated hydrocarbon thermosetting polymer are shown in Fig. 1. This is a semilogarithmic (Arrhenius) plot of resistivity versus temperature of a polymer after pyrolysis at progressively higher temperatures. This polymer exhibits the maximum values of $\rho(25°)$ and temperature-dependence after heating at 288° C. After pyrolysis at 302° C., a progressive decrease occurs in both parameters. The curve for temperature-dependence becomes almost flat after pyrolysis at 399° C. The large change in $\rho(25°)$ and temperature-dependence between the pyrolyses conducted at 385° and 399° C. suggests that the last significant amount of organic polymer has been burned off, leaving a residue which is almost entirely carbon.

Starting with nickel- and aluminium-doped ion exchange resins, Pohl and co-workers[5] have prepared semiconducting 'pyro-polymers' by this pyrolytic technique.

This technique is used in conjunction with differential thermal analysis and thermogravimetric analysis in investigations of the high-temperature characteristics of various polymers. It is suggested that it be standardized as a test method for determinations of thermal stability on bulk thermosetting polymers. Additional data on epoxide, epoxylated-novolac, polyurethane and silicone polymers together with a discussion of the degradation process in bulk thermosetting polymers will be published later.

Complexes of Zerovalent Vanadium, Chromium, Molybdenum and Tungsten with a Ditertiary Phosphine

We have previously reported that compounds of type [Mo(diphosphine)$_3$] are obtained from the reaction between dibenzenemolybdenum and the appropriate ditertiary phosphine[1], but we were unable to obtain analogous compounds of chromium by this method. We have therefore developed a direct method of preparation which, in addition to the molybdenum compound, has supplied the $Me_2PCH_2CH_2PMe_2$ complexes of vanadium(0), chromium(0) and tungsten(0) as listed in Table 1. These compounds were obtained by reducing a mixture of the metal chloride and three equivalents of the ditertiary phosphine in dry tetrahydrofuran. Lithium aluminium hydride (*A*) and sodium naphthalide (*B*) were used to effect reduction.

Table 1

Compound	Colour	m.p. (decomp.)	Reagent	Metal chloride
$[Cr\{C_2H_4(PMe_2)_2\}_3]$	bright yellow	309°	*A* or *B*	$CrCl_3$.3tetrahydrofuran
$[Mo\{C_2H_4(PMe_2)_2\}_3]$	yellow	397	*A* or *B*	$MoCl_5$*
$[W\{C_2H_4(PMe_2)_2\}_3]$	pale yellow	390	*A*	WCl_6*
$[V\{C_2H_4(PMe_2)_2\}_3]$	deep brown	254	*B*	VCl_3

* Reduced in tetrahydrofuran to 3-valent state before addition of ditertiary phosphine.

Reduction appears to be stepwise. For example, the VCl_3-diphosphine solution is deep green, and as reduction proceeds the colour changes through lavender blue to pale brown and is finally deep brown.

The compounds oxidize very quickly in air, and are decomposed by hydroxylic solvents, but have surprising thermal stability. They were purified by recrystallization from hot benzene, in which they are only sparingly soluble. The infra-red spectra of the compounds in 'Nujol' mulls are almost identical. $[V\{C_2H_4(PMe_2)_2\}_3]$ is paramagnetic ($\mu = 2{\cdot}10 \pm 0{\cdot}25$ B.M.), and its electron paramagnetic resonance spectrum is being investigated by Dr. J. F. Gibson of these Laboratories.

A full account of these and of similar compounds of other metals will be published later.

Stereochemistry of the Succinic Dehydrogenase System

IN continuation of work[1-3] on the stereochemistry of Krebs-cycle reactions, the stereochemistry of the succinic dehydrogenase reaction has been investigated with substrates that constrain the enzyme system to demonstrate its stereospecificity. These substrates are L-chlorosuccinic acid, newly found by us, and the L-enantiomorph of methylsuccinic acid; the racemic modification of the latter having been previously demonstrated[4,5] to decolorize methylene blue in the crude heart preparations.

Fig. 1 presents typical kinetic curves obtained by the Warburg technique for the uptake of oxygen by L-chlorosuccinic acid and L-methylsuccinic acid in the presence of Slater's succinic dehydrogenase preparation[6]. It is to be noted that the uptake of oxygen by L-chlorosuccinic acid is of the same order as that for succinic acid while that for methylsuccinic acid is decidedly less. The products of the oxidation were isolated and identified by chromatography[2] from the residue obtained by continuous ether extraction of acidified and deproteinized reaction mixtures. These products were, respectively, chlorofumaric acid and mesaconic acid (methylfumaric acid), thus establishing the dehydrogenation nature of the reaction and the fact that substituted fumaric acids results from the reaction. Of further interest is the fact that D-chlorosuccinic acid has but slight acitivity as a substrate and that D-methylsuccinic acid is not a substrate. The latter compound has been investigated for inhibitory properties by a spectrophotometric technique[7] and is a competitive inhibitor of succinate oxidation, K_I having the value $1{\cdot}2 \times 10^{-2}$ *M*, at *p*H 7·3 and 35·5°.

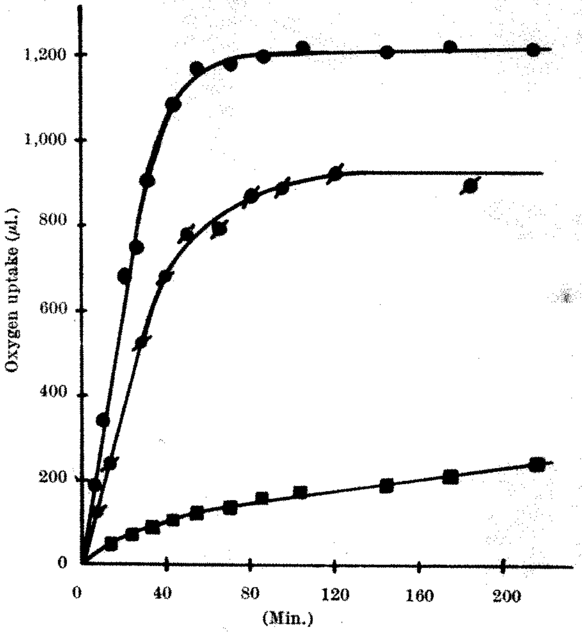

Fig. 1. Warburg oxidation of α-substituted succinic acids by succinic dehydrogenase at *p*H 7·3, 35·5°. Each reaction mixture contained 2·0 ml. succinic dehydrogenase suspension[6] and was 0·056 *M* in phosphate buffer, $6{\cdot}6 \times 10^{-4}$ *M* in methylene blue and 4×10^{-3} *M* in cyanide; total volume, 4·5 ml. ●, 0·018 *M* succinate; ⧫, 0·027 *M* L-chlorosuccinate; ■, 0·054 *M* L-methylsuccinate, 85 per cent optical purity

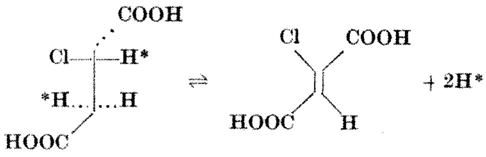
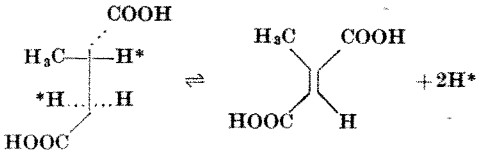
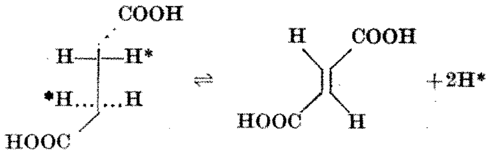
It is clear from these results that the succinic dehydrogenase system is, as expected, asymmetric in its action albeit this asymmetry cannot be detected with succinic acid by ordinary techniques[8]. The above results in conjunction with the recently, seemingly conclusive, demonstrated[9] trans-stereoselectivity of the succinic dehydrogenase system permits steric depiction of the reactions, as follows:



(1)

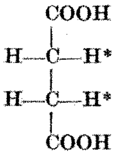


(2)



(3)

where the starred hydrogen atoms are those removed by the enzyme from L-chlorosuccinic acid (1) and L-methylsuccinic acid (2), while for succinic acid (3) the starred hydrogens are those that are removed from the enzyme-substrate complex, that is, the succinic acid molecule depicted may be rotated 180° around an axis perpendicularly bisecting the bond between the two α-carbon atoms and then placed in the enzyme to yield an enzyme-substrate complex that would lose the two unstarred hydrogens. The two hydrogens that are stereospecifically and stereoselectively removed from the enzyme-substrate complex may be called D-hydrogens, according to the projection formula:



and it is again to be noted that enzymes confer asymmetry on non-asymmetric molecules[10].

It is of interest to note that the succinic dehydrogenase system operates on L-substrates in a *trans* fashion as do *cis*-aconitase[2] and fumarase[3], and that the stereochemistry of the Krebs cycle may now be considered complete since the stereochemical pathway from fumaric acid to *iso*citric acid has been previously traced[8].

This investigation was supported in part by research grant *RG*-6245 from the Division of General Medical Sciences, U.S. Public Health Service.

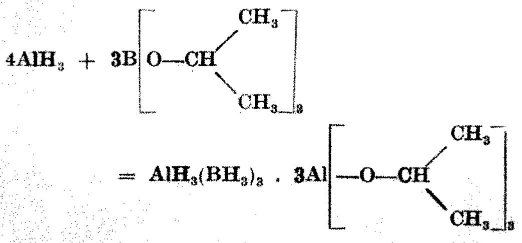
A New Class of the Complex Hydrides

While studying the reaction of aluminium hydride with esters of boric acid, the formation of a new type of the complex hydrides was observed. Thus, aluminium hydride reacts with *iso*propyl borate in ethyl ether, giving rise to a typical representative of the new type of hydride compounds:



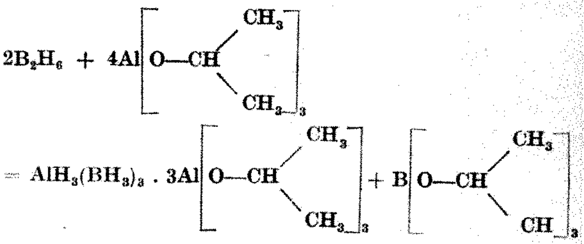
(I)

The product is a colourless liquid, distillable *in vacuo* (boiling point at about 120° C. at 0·5 mm. pressure, without decomposition). The yield is about 85 per cent. Analysis: $B_3Al_4H_{75}O_9C_{27}$ (molecular weight, calculated 684·25). B, 4·58 per cent; Al, 15·7 per cent; H, 11·05 per cent; H_{active} (assay by decomposition with diluted hydrochloric acid), 1·79 per cent. C, 45·95 per cent. Calculated values: B, 4·73 per cent; Al, 15·7 per cent; H, 11·01 per cent; H_{active}, 1·76 per cent; C, 47·3 per cent. Complex formation between complex borohydrides and alcoholates is not recorded in the literature, although the possibility of the formation of mixed crystals of lithium borohydride with lithium methoxide has already been considered[1].

The nature of the bonding in these new complexes is not known; their structure assigned above is confirmed by an alternate synthesis of (I) by the reaction of aluminium borohydride[2] with aluminium *iso*propoxide in tetrahydrofuran. Borane aluminium alcoholate is proposed as a generic name for these compounds. Thus (I) is borane aluminium *iso*propoxide. These compounds display a varying degree of sensitivity to air; they are handled preferably under pure nitrogen. The reaction is analogous to that of aliphatic or alicyclic borate esters, but with borate esters of phenols a different reaction occurs:

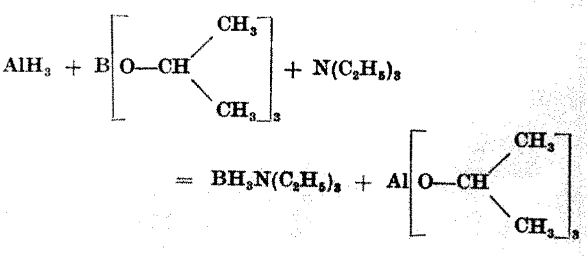
$$2AlH_3 + 2B(-O-C_6H_5)_3 = B_2H_6 + 2Al(-O-C_6H_5)_3$$

The diborane formed evolves from the ethereal reaction mixture after warming it up to 35° C. in a yield of about 70–80 per cent. Compounds of type (I) can be obtained with a 'reversed' method also. For example, diborane and aluminium *iso*propoxide react in tetrahydrofuran, giving rise to (I) and *iso*propyl borate:



This reaction is similar to that of diborane with the alcoholates of the alkaline metals[3].

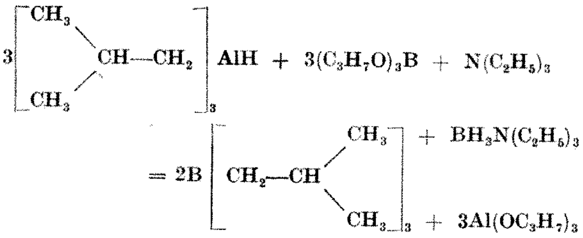
Sodium methoxide and lithium ethoxide give, with diborane, lithium borohydride and sodium borohydride, respectively. H. I. Schlesinger and co-workers treated aluminium alcoholates with diborane gas, but, using solid alcoholates, they obtained in a partial reaction an uncharacterized mixture of different products. The presence of amines completely changes the picture. Thus, aluminium hydride gives, with borate esters, in the presence of triethylamine triethylamine-borane (yield about 75 per cent) and aluminium alkoxide:



Borane aluminium *iso*propoxide is a strong reducing agent. It reduces many types of organic and inorganic compounds, for example, the carbonyl compounds to the corresponding alcohols, the esters to the primary alcohols, the nitriles to the amines. Its reducing strength probably equals the strength of aluminium borohydride. What seems important is that it is soluble and can be used in a broad range of solvents, for example, hexane, ligroin, mineral oil, ethyl ether, chloroform. No other hydride-type reducing agent is soluble in such a broad range of solvents.

The covalent, non-salt-like character and the strong reducing ability of these compounds agree with the correlation recognized earlier between these properties of the complex borohydrides[4].

As I found, the reaction of aluminium alkyl hydrides with borate esters gives products indicating that these compounds behave as mixtures of aluminium hydride and aluminium alkyls. For example, di-*iso*butyl aluminium hydride in the presence of triethylamine reacts with *iso*propylborate, giving rise to tri-*iso*-butylboron and triethylamine borane[5]:



$$3[(CH_3)_2CH{-}CH_2]_3AlH + 3(C_3H_7O)_3B + N(C_2H_5)_3 = 2B[CH_2{-}CH(CH_3)_2]_3 + BH_3N(C_2H_5)_3 + 3Al(OC_3H_7)_3$$

The complex aluminohydrides, for example $LiAlH_4$ and $NaAlH_4$, are transformable also, by treating them with borate or metaborate esters, to the corresponding borohydrides :

$$LiAlH_4 + B(OR)_3 = LiBH_4 + Al(OR)_3$$

The yields are 70–90 per cent; patients have been applied for.

BIOCHEMISTRY

Evaluation of the Activity of Corticosteroid 11β-Hydroxylase

2-METHYL-1,2-*bis* (3-pyridyl)-1-propanone (*SU* 4885) has been introduced as an agent for assessing pituitary–adrenal integrity and pituitary reserve[1]. The action of *SU* 4885 is to inhibit 11β-hydroxylation on the corticosteroid nucleus[2,3]. Administration of *SU* 4885 in the presence of a normal pituitary–adrenal relationship results in an increased excretion of 17,21-dihydroxy-20 ketosteroids as measured by the Porter–Silber[1] and ketogenic steroid reactions[4]. This increase is a resultant of the combined effect of decreasing 11β-hydroxylation, presumably increasing adrenocorticotrophic hormone production and increasing the production of 11-deoxycorticosteroids.

Since the inhibition of 11β-hydroxylation is not complete, situations may arise where there may not be a marked change in the total corticosteroid excretion even though there may be a positive adrenal response to *SU* 4885. In such cases the inhibition of the 11β-hydroxylase may still be present, and if one were to measure this inhibition more directly, it might be possible to determine whether there is a response to *SU* 4885 when the change in total 17,21-dihydroxy-20 ketosteroids is not marked. Where total corticosteroid excretion fails to rise, this may be due to failure of the *SU* 4885 to penetrate the adrenocortical cells, or to produce inhibition once it is there. An examination of the values of the 11 oxygenated steroids may present information on this point.

Evaluation of the action of *SU* 4885 should take into consideration the 11-oxy steroids as well as the 11-deoxy steroids. It is possible to separate 11-oxy from 11-deoxy 17-ketosteroids by employing column chromatography on alumina[5]. By means of the ketogenic reaction[6] the 17-OH-corticosteroids may be converted to 17-ketosteroids. These 17-ketosteroids may then be separated into the 11-oxy and 11-deoxy groups and each determined quantitatively by the Zimmermann reaction. The preformed 17-ketosteroids present in the urine are first reduced to alcohols by means of sodium borohydride in order to eliminate them from measurement. We have been utilizing the chromatographic method for the separation of 11-oxy ketosteroids from 11-deoxy ketosteroids and have combined this with the ketogenic reaction to study the effect of *SU* 4885 on human beings.

By expressing the results as the ratio of 11-deoxy : 11-oxy 17-ketogenic steroids, one has a more sensitive measurement of the action of *SU* 4885 than a measurement of total 17-OH-corticosteroids. Table 1 illustrates this by giving the values obtained for various individuals for the total ketogenic steroids and 11-deoxy : 11-oxy 17-ketogenic steroid ratios. It will be seen that even in cases where there were no marked increases in total ketogenic steroids, there were good-sized increases in the ratios. In case 5, there was a rather marked but unexplainable fall in total ketogenic steroids after the administration of *SU* 4885. There was, however, an increase in the 11-deoxy : 11-oxy 17-ketogenic steroid ratio. This technique of measuring the change in ratio may be a

Table 1. EFFECT OF *SU* 4885 ON TOTAL 17-KETOGENIC STEROIDS (KGS) AND 11-DEOXY : 11-OXY 17-KETOGENIC STEROID (KGS) EXCRETION IN URINE

relatively simple method for evaluating the action of *SU* 4885 where interpretation of results from determination of total corticosteroids may be ambiguous.

Recently, Butt *et al.*[7] have reported on a similar fractionation technique to investigate the effect of *SU* 4885. They utilized silica-gel chromatography to effect separation of the ketosteroids. Our results support the claim of Butt *et al.*[7] that the 'fractionation' method has greater sensitivity than the total 17-ketogenic steroid method.

We acknowledge the generosity of Ciba Pharmaceutical Products, Inc., Summit, New Jersey, for supplying the *SU* 4885.

The material for this work was made available from patients under the direction of Dr. Donald W. Petit and Dr. Colin Cooper at Los Angeles County General Hospital.

The Metabolic State of Thiosulphate

OUR earlier experimental work using labelled thiosulphate has shown that the two atoms of sulphur in this compound have different fates in the course of metabolism in the animal organism[1]. In rats, the inner sulphur atom is eliminated very quickly from the organism in the form of sulphate, while the outer atom is transformed into the sulphate much more slowly, going probably through a number of intermediate stages. The results of our investigations have shown that the thiosulphate may be the metabolic precursor of the sulphate, and that, however small its concentration in rat urine may be, the endogenous pool of thiosulphate is large (ref. 1*b*).

In the work reported here, rats were injected subcutaneously with 0·8 mgm. of D,L-cystine labelled with sulphur-35 dissolved in 0·5 per cent sodium carbonate, and at the same time with 200 mgm. non-radioactive sodium thiosulphate ($Na_2S_2O_3.5H_2O$). The dose of thiosulphate was repeated after 24 hr. The urine was collected quantitatively at set intervals of time. As a control, we used rats to which radioactive cystine had been given without the simultaneous administration of thiosulphate. The thiosulphate excreted in the collected urine was separated and estimated quantitatively by the method of Gast *et al.*[2], the residual sulphate was removed by adding barium chloride, and the remaining sulphur compounds which were neither thiosulphate nor inorganic sulphate were treated as residual sulphur. The total activity of a given sample of urine, the activity of the thiosulphate, and that of residual sulphur were determined. The activity of the inorganic sulphate was calculated indirectly from the difference.

Table 1. ACTIVITIES OF EXCRETED THIOSULPHATE, SULPHATE AND RESIDUAL SULPHUR

Results are expressed as a percentage of total activity of urine, after injection of 0·8 mgm. of cystine-^{35}S (4 animals)

Time (hr.)	Activity of thiosulphate		Activity of sulphate		Activity of residual sulphur

48–72	2·5–7·3	5·3	42·5–57·7	52	37·0–52·5	42·2

Table 1 shows the proportion of radioactivity of the different fractions of sulphur in urine after giving rats cystine alone. Table 2 similarly illustrates the results of experiments when both radioactive cystine and non-radioactive thiosulphate were injected.

As may be seen from Tables 1 and 2 only an insignificant percentage of activity is excreted in the form of thiosulphate after the injection of labelled cystine without the addition of thiosulphate. On the other hand, if at the same time a massive dose of unlabelled thiosulphate is given, 33 per cent of the sulphur produced by the metabolism of cystine is excreted in the urine in the form of thiosulphate in the course of 24 hr. Even after the next 48 hr., considerable quantities of radioactive thiosulphate are excreted when additional thiosulphate has been injected.

Our explanation of these facts is that external introduction of a large dose of thiosulphate inhibits the oxidation of the endogenic thiosulphate. We assume that thiosulphate given from an external source mixes with the pool of endogenous thiosulphate, and in consequence both the excretion and the oxidation of the endogenous thiosulphate take place at the same rate as that of the thiosulphate administered from an external source. A scheme of the relation between the exogenous and endogenous thiosulphate is given in Fig. 1, where $*A_0$ is the sulphur of the endogenous thiosulphate; $*A$ is the sulphur of the endogenous thiosulphate excreted in the urine in the form of thiosulphate; $*B$ is the sulphur in the

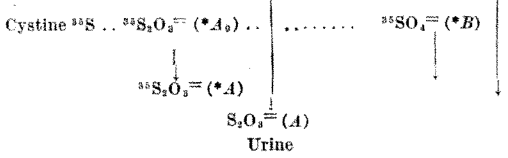

Fig. 1

sulphates originating from the radioactive cystine excreted in urine; A_0 is the sulphur of the injected thiosulphate; A is the sulphur of the injected thiosulphate excreted in the urine in the form of thiosulphate; B is the sulphur in the sulphates originating from the injected thiosulphate excreted in urine.

Quantitatively, if the endogenous and exogenous thiosulphate behave in an identical manner, the following relation would be valid: $^*A_0/^*A = A_0/A$.

We had previously estimated[1] that under normal conditions the rat excretes 0·05–0·1 mgm. of sulphur in the form of the thiosulphate and about 3 mgm. of sulphate sulphur during 24 hr.; that is, the ratio of these two kinds of sulphur may be expressed numerically as 0·01–0·03. The same relation exists between activity of thiosulphate and sulphate after injection of labelled cystine alone (Table 1). After injecting rats with labelled thiosulphate, we showed that the relation of excreted thiosulphate sulphur to the sulphate sulphur (A/B) is given by the average values 0·61, 0·19 and 0·53 for periods 0–6, 6–24 and 0–24 hr. respectively.

If we assume that thiosulphate is the normal precursor of the sulphate and that the small quantity in the urine is only the result of its rapid oxidation in the animal organism, after the injection of thiosulphate the ratio of the sulphur of the endogenous thiosulphate to the sulphur of the endogenous sulphate should be approximately the same as that of the introduced thiosulphate sulphur to the sulphate originating from this: $^*A/^*B = A/B$. Taking the figures from Table 2, we obtain the following values of $^*A/^*B$: 0·99, 0·11, 0·67 for periods 0–6, 6–24 and 0–24 hr. respectively.

The figures obtained for $^*A/^*B$ as compared with values of A/B lie in the range of experimental deviation and these results indicate with great probability that the endogenous thiosulphate behaves like the exogenous, and hence it is the fundamental precursor of the sulphate originating in the organism of the rat.

A full description of the experiments and calculations will be given elsewhere.

Polysaccharides of *Mycobacterium phlei*

INVESTIGATIONS of the polysaccharides of *Mycobacterium phlei* have been few and mainly concerned with those secreted into the culture medium. Thus Masucci and McAlpine[1] found that a polysaccharide which they isolated from culture filtrates contained D-mannose and D-arabinose. Tennent and Watson[2] isolated a similar product and showed that the molecular weight was 7,300. In the present investigation the intracellular polysaccharides of *M. phlei* were studied.

The organisms were grown on a culture medium (10 litres) consisting of 'Oxoid' bacteriological peptone, 1 per cent; 'Lab. Lemco', 1 per cent; sodium chloride, 0·5 per cent, and glycerol, 5 per cent at 37° for 16 days. The cells were separated from the medium, washed with 0·14 *M* sodium chloride, suspended in phosphate buffer, *p*H 8, and disintegrated in batches of 250 ml. by shaking at 0° for 5 hr. with ballotini glass balls (1 mm. diameter) in a vibratory ball mill. The suspension of broken cells was diluted to 1 litre with phosphate buffer, *p*H 8, and then adjusted to *p*H 4 with dilute acetic acid. The suspension was centrifuged at 2,600 r.p.m. at 0° and the precipitate (cell debris, nucleoproteins, etc.) discarded. The supernatant liquids from the various batches were combined, concentrated to 1 litre by freeze-drying and then mixed with 5 volumes of ethanol. The precipitate so produced was centrifuged off, dissolved in distilled water, dialysed and freeze-dried to give a crude polysaccharide fraction (12 gm.), $[\alpha]_D^{20} + 164°$; N, 0·6 per cent; P, 0·2 per cent. Examination of acidic hydrolysates showed the presence of glucose and small amounts of mannose and arabinose. The presence of glycogen was indicated by the formation of a brown colour with iodine.

The crude polysaccharide (5·9 gm.) was fractionated further by the use of cetrimide ('Cetavlon', Imperial Chemical Industries Pharmaceuticals, Ltd.) in the presence of borate[3]. Four fractions were obtained; fraction I (30 mgm.) was precipitated at *p*H 7·5, and, after acid hydrolysis, contained arabinose, glucose, mannose and amino-acids; fraction II (4·5 gm.) was precipitated at *p*H 9·5 and contained only glucose; fraction III (40 mgm.) was precipitated at *p*H 10 and contained glucose and a trace of mannose, and fraction IV (0·6 gm.) did not precipitate with cetrimide–borate and contained mainly arabinose, a smaller amount of mannose, some glucose and a trace of ribose. Fraction IV was isolated by dialysing the supernatant liquid, freeze-drying and extracting the dry solid with chloroform to remove the cetrimide.

The major fraction (fraction II) was glycogen as shown by the infra-red spectrum (peaks at 930, 845 and 758 cm.$^{-1}$), which was identical with that of an authentic sample of liver glycogen examined at the same time[4], and by the production of a brown colour with iodine. The absorption curve of the iodine complex had $\lambda_{\max.}$ 390 mμ. This was lower than that of other glycogens[5], for example, *Myletus edulis*, 420 mμ, rabbit liver, 490 mμ, and *Bacillus megaterium*, 520 mμ. The intensity of absorption was also lower (E_{390} 0·27 with 0·1 per cent glycogen in 0·01 per cent iodine and 0·2 per cent potassium iodide). The $\lambda_{\max.}$ was somewhat variable; another sample had $\lambda_{\max.}$ 405 mμ. The glycogen fraction was homogeneous when examined by boundary electrophoresis in borate buffer *p*H 9·2. The polysaccharide also migrated towards the anode in veronal buffer *p*H 9·2, but much more slowly than in borate. This may have been due to the presence of a small number of phosphate groups (phosphorus content, 0·03 per cent).

The second major fraction (fraction IV) contained 3 per cent nitrogen, which was due to the presence of protein and a small amount of nucleic acid; no amino-sugars could be detected. The fraction was heterogeneous when examined by boundary electrophoresis, containing at least two components when examined in borate, *p*H 9·2, glycine, *p*H 9·8, and veronal, *p*H 8·6. The migration in the glycine and veronal buffers could be due to the presence of protein in the fraction. Attempts to remove the protein by precipitation with trichloroacetic acid or by denaturation by shaking with chloroform–octanol (9 : 1) were unsuccessful and resulted in the production of fractions containing different proportions of protein. These results indicated that fraction IV was a mixture of polysaccharide–protein complexes.

When the organisms were grown on a medium which contained 0·4 per cent ammonium lactate instead of 5 per cent glycerol, no glycogen could be isolated from the cells, the polysaccharide being essentially similar to fraction IV. The organisms isolated after growth in 90 litres of a medium containing 'Oxoid' bacteriological peptone 1 per cent, 'Lab. Lemco' 0·5 per cent, sodium chloride 0·5 per cent and ammonium lactate 0·4 per cent for 16 days at 37° were washed free from medium and disintegrated by shaking with ballotini glass balls at 0°. The broken cells were extracted at *p*H 8, and the suspension then adjusted to *p*H 4, centrifuged at 2,600 r.p.m., and the supernatant liquid decanted. The process of extraction at *p*H 8 and reprecipitation at *p*H 4 was repeated twice on the precipitate and the three supernatant liquids were combined and treated with 3 vol. of ethanol. This material contained a considerable amount of nucleic acid which was then removed by precipitation as the lanthanum salt. The resulting polysaccharide (1·74 gm.) isolated from the non-precipitable fraction was similar to fraction IV described above in containing protein (nitrogen content, 5·2 per cent) which could not be easily removed and in being electrophoretically inhomogeneous. No glycogen could be detected by means of iodine.

This material (fraction V ; 1·7 gm.) was further separated into two components by precipitation with 50 per cent ethanol in the presence of 0·01 *M* zinc sulphate. The precipitate (fraction V*a* ; 790 mgm.) still contained protein (N, 5·0 per cent), and paper chromatographic examination of acid hydrolysates showed that mannose and glucose were present in a proportion of 5 : 1 and that arabinose was absent. The supernatant fraction also contained protein, and acid hydrolysates contained arabinose and a little mannose. This fraction was not investigated further.

Fraction V*a* had $[\alpha]_D^{20} + 20°$ in water and an infra-red spectrum which showed peaks at 975, 905, 880 and 810 cm.$^{-1}$. Further purification was carried out by the use of Fehling's solution, which is known to precipitate mannans[6]. The precipitate so produced was dissolved in dilute acid, dialysed and freeze-dried. This purified product (30 per cent by weight of fraction V*a*) contained mannose and glucose (5 : 1) and 0·96 per cent nitrogen. A positive optical rotation ($[\alpha]_D^{20} + 67°$ in water) indicated that it was probably an α-glucomannan. Examination in the ultracentrifuge (kindly carried out by Dr. D. R. Stanworth) showed the presence of three components ; one was a minor one (10 per cent) and the other two were only partly resolved even after prolonged centrifuging at 60,000 r.p.m. The infra-red spectrum in the region 1,000–800 cm.$^{-1}$ was similar to that of fraction V*a*. The spectrum had some similarities with that of a sample of yeast α-mannan (peaks at 975, 917, 885 and 813 cm.$^{-1}$) and with that of α-glucomannan II isolated from yeast cell walls by Kessler and Nickerson's method[7] (peaks at 980, 915, 890 and 815 cm.$^{-1}$) but they were not identical.

It can be concluded, therefore, that at least three intracellular polysaccharides are produced by *M. phlei*, a glycogen, an α-glucomannan and a polysaccharide containing mainly arabinose.

We thank Prof. M. Stacey for his interest and Mr. E. T. J. Chelton and Mr. C. G. James for technical assistance. Thanks are also due to the Medical Research Council for financial assistance. We are also grateful for the award to one of us (M. N.) of a scholarship under the Colombo Plan.

Distribution of Cholinesterase within the Kidney of the Domestic Fowl

DURING investigations in this laboratory it was noticed that the distribution of cholinesterase within the fowl kidney was not uniform. The following observations are recorded in view of the sparse information regarding cholinesterases in the bird. The nomenclature of Augustinsson and Nachmansohn[1] is used throughout.

Males and females 12–14 weeks old were killed by an overdose of nembutal, the kidneys excised and frozen sections cut at 50μ and stained for true cholinesterase[2]. It was also possible to obtain paraffin sections by slightly modifying the technique ; slices 1 mm. thick were cut from the kidney and left in the substrate for 18 hr. at 37° C. The subsequent treatment was as given by Coupland and Holmes[2]. The tissue was then embedded in paraffin and sectioned in the normal way. With this procedure the very heavy deposit on the surface of the block tended to obscure a certain amount of detail, but thin sections were obtained and gave the same results as the frozen sections. In both methods pseudocholinesterase was also demonstrated by substituting butyrothiocholine iodide as substrate, and controls were obtained by preliminary incubation of the sections in 1×10^{-7} di-*iso*propylfluorophosphonate[3]. No distinction could be made between kidneys obtained from males and females.

The distribution of both true and pseudocholinesterase appeared to be very similar, but the degree of staining for the two enzymes differed considerably. Both were found in quantity in the vascular system, although this would be expected since it has been shown that cholinesterase, either the pseudo-enzyme or a mixture of true and pseudocholinesterase, is present in avian plasma[4]. The ureter wall stained very heavily for both enzymes (Fig. 1), but the tubule walls appeared to be free (Fig. 2). No cholinesterases were found in the contents of the lumen of tubules or ureters (Figs. 1, 2). Perhaps of greater importance was the heavy staining of the Bowman's capsule, particularly for true cholinesterase (Fig. 2), and this may be related to the presence of these enzymes in avian plasma. However, neither enzyme was found in the tubule or uretal contents, which suggested that

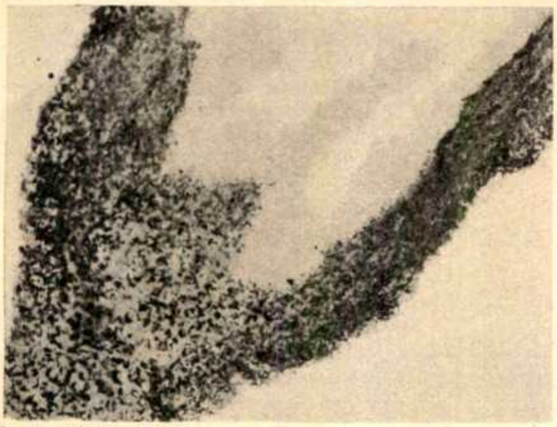

Fig. 1. Ureter. Localization of true cholinesterase only in the wall of the ureter. Frozen section

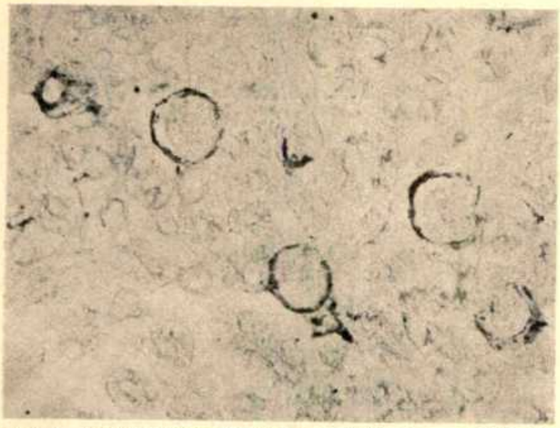

Fig. 2. Kidney section showing true cholinesterase activity in Bowman's capsule. The tubule wall and contents have not taken the stain. Paraffin section

they are not being excreted except in amounts very much lower than in plasma or in changed form.

It has been suggested that cholinesterase is involved in the sodium pump mechanism[5], and it is therefore possible that the presence of these enzymes in Bowman's capsule is related to kidney function. This suggestion must remain speculative until more is known about the physiological significance of these enzymes.

Hæmolytic Activity of Colloidal Silica

COLLOIDAL silica is highly toxic when administered parenterally[1,2]. In isolated biological systems silica has been shown to interfere with some enzymes[3,4], activate blood clotting and pharmacologically active substances in plasma[5] and interfere with the red cell envelope[6]. Most of these effects are probably due to the adsorption and partial denaturation of proteins at the surface of silica particles[5,7].

The ultimate particle size of the colloid varies with the conditions of preparation and storage. Most of the investigators quoted have observed that aged sols have far greater biological effects than freshly prepared silicic acid solutions[2–6]. The difference is presumably due to the spontaneous growth of the particles on ageing. Using modern methods it is now possible to make silica dispersions of almost any desired particle size and thus evaluate quantitatively the differences between their biological activity. Such observations have been reported by one of us in relation to clotting of blood[8]. In the present work we have studied the effects of various types of colloidal silica on intact red cells.

To obtain silicic acid, 1–5 per cent solutions of sodium silicate were passed through a column of cation exchange resin ('Zeo-Karb 225'). According to the concentration, *p*H and subsequent heating of the material, a series of sols of particle size from 2 mμ to 6mμ were obtained (cf. Iller[9]). In addition we used commercial preparations of silica ('Ludox *SM*', Du Pont: 7 mμ and 'Syton *W*20', Monsanto: about 30 mμ).

Human red cells were washed three times with buffered isotonic saline (phosphate or bicarbonate buffer, *p*H 7·4) and suspended in saline. One-tenth volumes of serial dilutions of silica were then added to a series of tubes with the red cell suspensions and the contents were incubated at 37° C. with occasional gentle agitation. After centrifuging, the supernatant hæmoglobin was measured and expressed as a percentage of the total.

Fig. 1 shows the result of a typical experiment with a 2 per cent cell suspension incubated with silica for 30 min. It is obvious that colloidal silica can be a very potent hæmolytic agent. For example, 1 μgm./ml. of the 30-mμ particles lyses about 50 per cent of the cells. Since the surface area of this silica is somewhat less than 1 cm.^{2}/μgm. while that of 2 per cent cell suspension is about 150 cm.^{2}/ml., it follows that contact of silica with a very small portion of the red cell surface is sufficient to produce hæmolysis. The hæmolytic activity decreases with the particle size

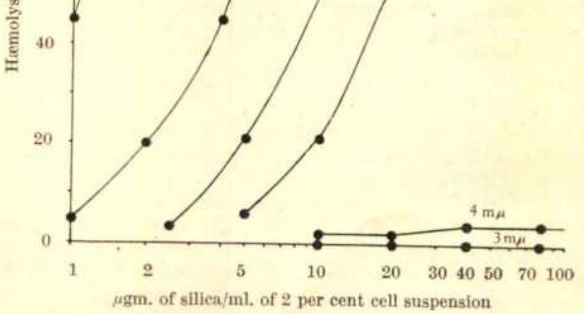

Fig. 1. Hæmolysis of 2 per cent red cell suspension incubated with colloidal silica for 30 min. at 37° C. The figures above the curves indicate the mean particle diameter of the colloid

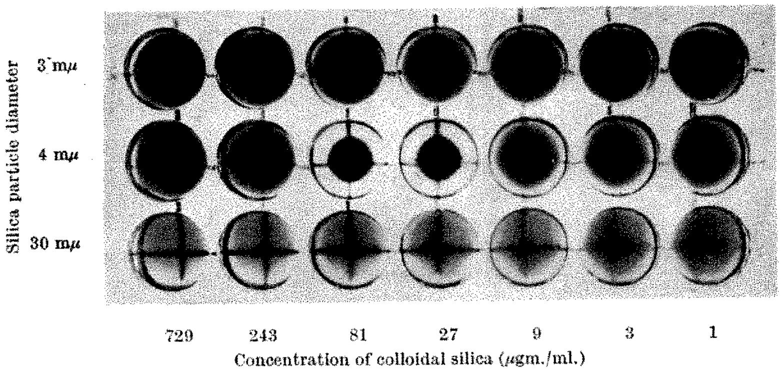

Fig. 2. Hæmagglutination plate viewed from above. 2 per cent red cell suspension was incubated with colloidal silica. Black lines were drawn on the reverse side to emphasize the transparency of the hæmolysed samples. Top row, no visible change; second row, zonal agglutination; bottom row. hæmolysis

of the colloid until it becomes negligible at about 4 mμ diameter. We have also observed that particles in the range of 3·5–7 mμ have a powerful agglutinating effect on the red cells, with a well-marked prozone (Fig. 2). Silica of 3-mμ or smaller particle size has no such activity but protects the cells against the agglutination and hæmolysis by the larger particles. This 'blocking' effect occurs only when the smaller particles are introduced into the cell suspension before the larger ones and it persists after repeated washing with saline, which probably indicates an irreversible adsorption of silica on to the erythrocyte surface. Such 'coated' red cells have other properties in addition to their resistance to the larger particles of silica. Thus they are not hæmolysed by streptolysin *O* and the saponin fragility is somewhat decreased. On the other hand, these cells become more susceptible to immune (rat) hæmolysins and to primaquine. The osmotic fragility is not altered, nor is there any obvious abnormality in appearance except that the cells do not become spherocytic when examined between glass slides and coverslips as do normal washed erythrocytes[10].

In all these experiments it is essential to use well-washed cells because even small traces of plasma markedly inhibit the action of silica. The addition of 1 : 200 plasma to the system as in Fig. 1 completely prevents hæmolysis. The plasma must, however, come in contact with silica before the latter is adsorbed by the red cells. Even a few seconds delay suffices to abolish the protective effect of the plasma. This phenomenon is evidently due to the coating of the silica by certain plasma components. The substances in question are non-dialysable and can be recovered in alkaline eluates from powdered silica which has been exposed to plasma or serum. Such eluates retain their activity after heating to 100° C.

Our observations on the agglutinating and blocking activity of silica agree with the qualitative findings of Renton and Hancock[6], who suggested that these effects may be analogous to those of agglutinating and incomplete antibodies, respectively. The present results extend this model to cover hæmolysis as well.

Although our present knowledge of the red cell structure is still fragmentary, the reaction between silica and the cell membrane may be visualized in general terms as a two-stage process: first, a rapid adsorption of the particles by the cell surface, due mainly to the ionic attraction between silica and the amino-groups at the cell surface and further reinforced by hydrogen bonds and van der Waals forces[7]; secondly, protein denaturation, the extent of which may depend purely on the geometrical relation between the colloidal particles and the protein molecules, as was previously suggested in connexion with blood clotting[5,8]. Individual silica particles of less than 3·5 mμ may not provide sufficient contiguous surface to permit significant unfolding of the much larger protein molecules. Contact with larger particles will, however, allow such unfolding (denaturation), and the resulting interference with the integrity of the cell membrane then leads to agglutination or hæmolysis according to the degree of denaturation. The geometrical picture may, of course, be over-simplified and other physical differences between the large and the small colloidal units may be contributory factors[11]. Despite these reservations, colloidal silica may prove a useful tool in the elucidation of the red cell structure.

We wish to thank Miss Helen Robin for technical assistance.

PHYSIOLOGY

The Psychotomimetic Properties of 3,4,5-Trimethoxyamphetamine

dl-3,4,5-TRIMETHOXYAMPHETAMINE (*dl*-TMA), first prepared as a homologue of mescaline in 1947 [1], has remained to a large measure unexplored. A single paper has described its effects in human subjects[2], demonstrating that the drug allows stroboscope-induced hallucinations at the levels employed, namely, 0·8–2·0 mgm./kgm., orally. In the present work, *dl*-3,4,5-trimethoxyamphetamine was synthesized by the general method of Ramirez and Burger[3] and was chemically identical to that previously described[1]. Pharmacological similarity was demonstrated by the administration of between 1·6 and 2·0 mgm./kgm. as the hydrochloride, to three adult male subjects. The responses were found to be parallel in intensity and duration to those described earlier[2], although the vivid hallucinations reported were not observed.

It has been found, however, that with an increased dosage of the drug, the psychotropic response changed in a most dramatic manner. Dosages of 2·8–3·5 mgm./kgm. were given to five adult male subjects, all of whom had had previous experience with either mescaline or lysergic acid diethylamide.

The physical changes observed were similar for all subjects employed. In each case, after about half an hour, there ensued a period of autonomic distress, characterized by sweating, tremor, and chills as well as nausea and dizziness. This phase lasted no more than an hour. The slight but definite systolic blood pressure increase of about 10 mm. mercury returned to normal at the end of this phase. The concurrent diastolic increase was barely perceptible (*c.* 2 mm. mercury). During the remainder of each experiment (approximately another 6–8 hr., which includes the period of extreme mental derangement described below) very few overt physical signs of drug effect were evident. Pupillary dilatation and slight motor inco-ordination were noted. Pulse increase was negligible.

The psychic changes observed, however, were extreme and showed considerable individual variability. The initial effects, at about 2 hr. from the ingestion of the drug, were mescaline-like, involving intensification of visual experience, including amplification and distortion of colour, texture, form, and spatial relationships. These effects were distinctly less than those expected from a pharmacologically equivalent dose (2 ×) of mescaline. Auditory and tactile sensations were also intensified, and both paræsthesia and synæsthesia were noted on occasion. None of the subjects displayed the enhanced capacity for empathy characteristic of mescaline.

The emotional responses elicited during the period of maximum *dl*-3,4,5-trimethoxyamphetamine intoxication (3–5 hr. from the start of the experiment) were striking in their intensity. Anger, hostility, and megalomaniac euphoria dominated the subject's thoughts and conversation. Actual acts of hostility were not observed, but it was felt that, in at least two subjects, provocation would have precipitated homicidal violence. All subjects reported imagery, either patterned or scenic, with eyes closed. Recollection of past experiences did not seem to be enhanced, and intellectual performance appeared to be somewhat impaired. Once the plateau of intoxication had passed, return to normal was rapid. The subjects experienced no clouding of consciousness, and subsequent recall of events was excellent.

Due to the unexpectedly anti-social character of the response to larger doses of the drug (a response unobserved in more than 40 mescaline subjects), a warning concerning adequate supervision during experimentation with this new drug seems desirable.

Investigations employing the optical isomers, as well as structural homologues, of *dl*-3,4,5-trimethoxyamphetamine are in progress.

The Conversion Ratio as a Discriminatory Test for Thyroid Activity in Fish

THE rate of conversion of administered inorganic radioiodine into protein-bound radioiodine of the plasma has been used frequently to evaluate thyroid activity in mammals. The test is recognized as having good discriminatory power in higher vertebrates[1,2], but the relatively large sample of blood required for separation of serum by the usual methods has made the test impractical for small fish. A method is described here for determining protein-bound radioiodine as an *in vivo* test in fish of 30 gm. or more and as a terminal test in fish as small as 1 gm.

Each fish received an intraperitoneal injection of carrier-free iodine-131, the dosage depending on the weight of the fish and the detection instrument used. When using a scintillation well-counter, the instrument of choice, 0·1 μc. iodine-131 per gm. body-weight was sufficient. Blood sampling for *in vivo* determinations in anæsthetized trout were carried out by direct cardiac puncture with a ¼ c.c. heparinized syringe. Blood was transferred to a heparinized capillary tube and the vacant end of the tube plugged with 'Plasticene' or sealed with a small concentrated flame such as that of a propane torch. Blood may be obtained from very small fish by cutting off the tail and collecting the blood as it flows from the caudal artery into a heparinized capillary tube. Sealed tubes were centrifuged in a hæmatocrit centrifuge or in a 15-ml. bucket centrifuge fitted with hollow wooden adapters for the tubes. After separation of the cells, the tubes were scratched and broken between cells and plasma and the plasma was expressed into a 15-ml. centrifuge tube containing 2 ml. of 20 per cent trichloroacetic acid. The protein precipitate was stirred vigorously with a glass rod and centrifuged down. The supernatant containing the inorganic iodine-131 was decanted and saved. The precipitate was washed three times with 2-ml. portions of 2·5 per cent trichloroacetic acid, each time breaking up and stirring the precipitate and then centrifuging. All trichloroacetic acid washes, totalling 8 ml., were combined and saved. The precipitate was then dissolved in sodium hydroxide and diluted to the same volume as the combined supernatant washings. Finally, the radioactivity of both fractions was counted. Using the well-crystal scintillation counter, aliquots of supernatant and dissolved precipitate were pipetted into counter tubes and counted to 10,000 counts. An end-probe scintillation counter was occasionally used, and greatest sensitivity was achieved by securing the probe with crystal facing up in a lead castle and placing the fractions contained in a small beaker directly on the crystal. After subtraction of the background count, percentage of protein-bound iodine-131 is calculated as :

$$\frac{\text{Prot.-bound iodine-131 in counts per min. (precip.)}}{\text{Prot.-bound iodine-131 + iodine-131 (combined counts of precip. and supernat.)}} \times 100$$

Serial determinations in rainbow trout (*Salmo gairdneri*) and starry flounder (*Platichthys stellatus*) have shown that protein-bound radiothyroxine in the plasma gradually increases relative to inorganic radioiodide until approximately the fourth or fifth day, after which it begins to fall. The rate of increase usually is most rapid just before the inflexion and represents the period when the greatest percentage

Table 1.' COMPARISON OF THYROID RADIOIODIDE UPTAKES AND CONVERSION RATIOS IN NORMAL AND THIOUREA-TREATED FLOUNDER

Controls		Thiourea-treated	
4-day uptake	4-day conversion ratio	4-day uptake	4-day conversion ratio
6·40	14·3	2 05	1·10

8·90	13·8	2·93	0·54
		2·05	0·42

of labelled thyroxine molecules is secreted from the thyroid gland. When breakdown or excretion of radiothyroxine exceeds its rate of appearance in the blood, the conversion ratio falls.

Usually only one determination is made at a fixed interval of time after the injection of radioiodide. Sampling should be made before the maximum value for protein-bound iodine-131 is reached, and the ideal time to sample will vary with the species and with the experimental conditions. In general, the more active the thyroid gland, the earlier the ideal sampling time will be. A 4-day interval between administration of the tracer dose and sampling has been found satisfactory for rainbow trout and starry flounder under normal conditions. Periods longer than 4 days rarely prove worth while, because the reliability of the method is rapidly limited by loss of radioiodide through excretion and physical decay.

In Table 1 the 4-day conversion ratios and the 4-day thyroid radioiodide uptakes of normal starry flounder and flounder immersed 11 days in 0·04 per cent thiourea are compared. In this experiment, the 4-day conversion ratio is of far greater value than thyroid radioiodide uptake for determining the degree of thyroid inhibition achieved. The conversion ratios average 14·6 for the normal flounder as compared with 0·42 in those flounders treated with thiourea; this shows that blockage of hormone synthesis is essentially complete. Thyroid radioiodide uptake is comparatively useless for such a test, because some radioiodide is accumulated by the inhibited gland.

It is desirable to reduce the time-interval before sampling if the experimental treatment is expected to stimulate thyroid activity greatly. Table 2 shows the 2-day conversion ratios of starry flounder treated with thyroid-stimulating hormone. Two injections of the hormone were given, one three days and the other six days before the injection of radioiodide for the determination of protein-bound iodine-131.

In spite of the small size of sample, the relative effectiveness of the different dosages of thyroid-stimulating hormone is easily estimated.

Many factors influence the conversion ratio, making its mathematical analysis exceedingly complex[3].

Table 2. EFFECT OF THYROID-STIMULATING HORMONE ON THE 2-DAY CONVERSION RATIO OF STARRY FLOUNDER (*Platichthys stellatus*)
Experimental temperature, 14·0° C.; experimental salinity, 26 per mille

Controls		Treated with thyroid-stimulating hormone

	av. 1 72		av. 6·7		av. 25·4		av. 40·5

However, for purposes of distinguishing different levels of thyroid activity, the test is accurate, simple to perform and possesses greater discriminatory power than the uptake of radioiodide by the thyroid gland. It has the important advantage of measuring the relative rate of secretion of thyroid hormone rather than the more indirect iodide-trapping activity of the thyroid gland. The test should prove particularly valuable in assessing thyroid activity of very small fish.

Thyroid-stimulating hormone was kindly supplied by Wayne Donaldson, of Parke, Davis and Company, Detroit. Financial assistance was received through grant *G*-8502 of the National Science Foundation, Washington, D.C., awarded to W. S. Hoar, University of British Columbia.

Transport of Phosphate into the Erythrocyte

THE active transport of inorganic phosphate into the red blood cell is generally believed to be closely related to glycolysis, although the actual mechanism of transfer is unknown[1]. Gourley[2] considered that phosphate enters the erythrocyte through the formation of adenosine triphosphate at the cell surface. Prankerd *et al.*[3] and Bartlett[4] concluded from their investigations that inorganic phosphate is transferred into the cell by incorporation into 1,3-diphosphoglyceric acid. Our own experimental evidence suggests that the transfer of inorganic phosphate is independent of glycolysis.

Whole blood was incubated at 37° C. with orthophosphate labelled with phosphorus-32. The disappearance of phosphorus-32 from the plasma was measured over a 2-hr. period and calculated on the basis of a 40 per cent hæmatocrit. In a series of eight samples the rate of disappearance of phosphorus-32 in the presence of glucose (200 mgm. per cent) was 29·3 per cent/hr. ± 3·1 per cent. When iodoacetic acid was included in the incubation mixture to a final concentration of 10^{-3} molar, lactic acid production was completely inhibited, and phosphorus-32 left the plasma in nine samples at a mean rate of 12·5 per cent/hr. ± 1·1 per cent. Eight samples of whole blood incubated with glucose, iodoacetic acid and adenosine (6·25 m.mol./l.) were found to show a rate of disappearance of plasma phosphorus-32 similar to those samples incubated with glucose alone (29·8 per cent/hr. ± 3·7 per cent). Under these conditions there was again no production of lactic acid. The similarity of the two rates of influx with glucose alone, and with glucose, iodoacetic-acid and adenosine suggests that the mechanism of transfer of phosphate into the cell under these two conditions may be identical. To establish further the similarity of transport in the presence or absence of glycolysis we studied the effects of variation of incubation temperature and of external phosphate concentration on the rate of entry of phosphate into the erythrocyte.

In Fig. 1, it will be noted that as the external phosphate concentration is increased there is an increase in the rate of entry of orthophosphate into the red cell. This increase is identical in the presence of either glucose, or glucose, adenosine and iodoacetic acid. In Fig. 2, the effect of change of temperature is shown. An increase in temperature causes an increase in the transfer-rate constant which is identical under both conditions. These findings indicate that phosphate enters the red blood cells at similar rates whether glycolysis is proceeding or not.

To find out whether the phosphate which entered the cell under these two conditions would be metabolized in a similar fashion the distribution of radioactive phosphorus-32 within red cell phosphate esters was studied by the method of anion exchange column chromatography of Bartlett[3]. It may be seen in Fig. 3 that in the presence of glucose most of the phosphorus-32 was found in adenosine triphosphate (ATP) and 2,3-diphosphoglyceric acid (2–3 DPG) (Fig. 3, *A*). Inhibition of glycolysis by iodoacetic acid (Fig. 3, *B*) prevented the entry of ^{32}P-orthophosphate into these esters. When adenosine was included radioactivity was found in the 0·1 *N* ammonium chloride fraction, with very little in adenosine triphosphate (ATP) or 2,3-diphosphoglyceric acid (2–3 DPG) (Fig. 3, *C*). In *A* and *B* the amount of organic phosphate in the 0·1 *N* ammonium chloride fraction (known to contain hexose diphosphates but no monophosphate[5]) was low. In *C*, however, this fraction contained greater quantities both of organic phosphate and fructose. Fructose was determined by the Roe modification of the Seliwanoff procedure[6]. In two experiments it was found that the excess phosphate and fructose in *C* occurred in the ratio of 1·83 moles of phosphorus/mole of fructose. These findings suggested that the radioactivity which appeared in the 0·1 *N* ammonium chloride fraction under these conditions was in fructose-1,6-diphosphate.

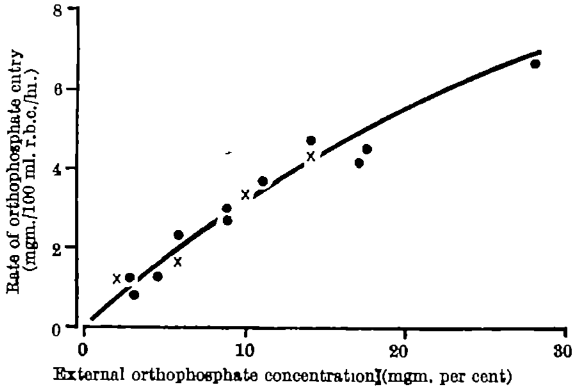

Fig. 1. Effect of variation of external phosphate concentration on the rate of total phosphate entry into the red blood cell. Washed erythrocytes were suspended in veronal acetate buffer (pH 7·45); and incubated for 2 hr. at 37° C. with 0 2 μc. phosphorus-32 sodium phosphate in the presence of: (1) glucose 200 mgm. per cent (●); (2) glucose 200 mgm. per cent, iodoacetic acid 10^{-3} *M* and adenosine 6 25 m*M* (×)

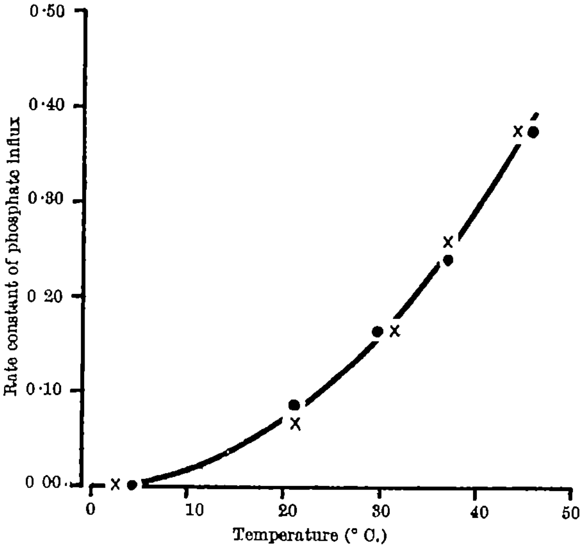

Fig. 2. Effect of variation of incubation temperature on the rate constant of phosphate influx into red blood cells. Washed erythrocytes were suspended in veronal acetate buffer (pH 7 45, inorganic phosphate concentration 8 0 mgm. per cent). These cells were incubated for 2 hr. at 37° C. with 0·2 μc. phosphorus-32 sodium phosphate in the presence of: (1) glucose 200 mgm. per cent (●); (2) glucose 200 mgm. per cent, iodoacetic acid 10^{-3} *M* and adenosine 6·25 m*M* (×).

Rate constant of phosphate influx in each experiment was corrected to a hæmatocrit of 40 per cent

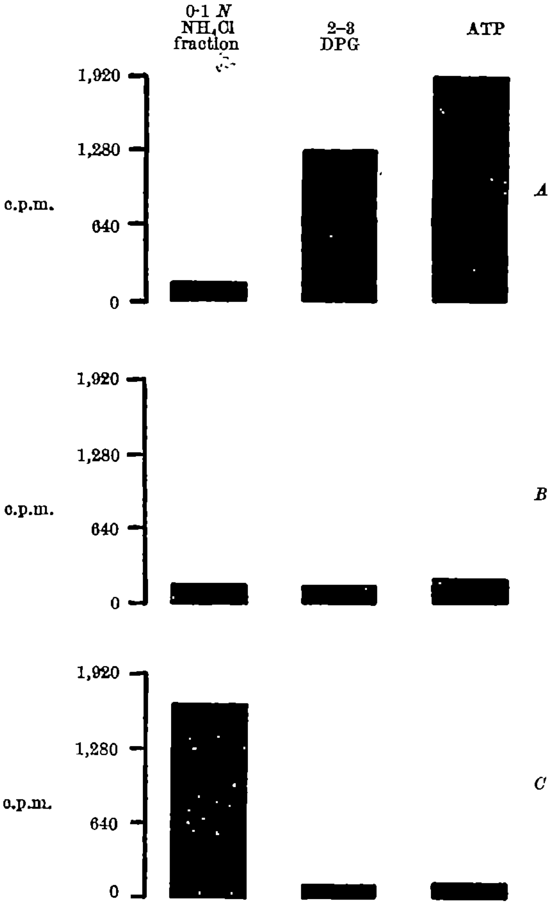

Fig. 3. The radioactivity (c.p.m.) of erythrocyte phosphate esters after 2-hr. incubation at 37° C. (20 ml. of blood with 20 μc. of phosphorus-32) in the presence of: *A*, glucose (200 mgm. per cent); *B*, glucose (200 mgm. per cent) and iodoacetic acid 10^{-3} *M*; *C*, glucose (200 mgm. per cent), iodoacetic acid 10^{-3} *M* and adenosine 6·25 m*M*

In the presence of glucose alone (Fig. 3, *A*) orthophosphate is probably esterified by way of the glyceraldehyde-3-phosphate dehydrogenase reaction. With glucose, iodoacetic acid and adenosine, glycolysis is inhibited and inorganic phosphate is esterified, presumably in the purine nucleoside phosphorylase reaction, to form ribose-1-phosphate. This material can then be metabolized through the hexose monophosphate shunt and result in an accumulation of fructose-1,6-diphosphate[7]. Under these two conditions inorganic phosphate enters the red blood cell at the same rate yet follows different metabolic pathways. The identical kinetics of phosphate transfer, whether glycolysis is active or inhibited, suggests that the limiting step of entry of phosphate into the red blood cell is similar under both conditions and is not dependent on glycolysis.

Control of Fertility by 6-Azauridine

We have previously suggested that agents known to inhibit cell division might be effective ovicides in mammals, in amounts which are non-toxic to the pregnant female[1]. We have reported on a few such agents, and our results in general supported the hypothesis that it might be possible to separate the effects on the ovum and on the maternal organism[2]. Since that time, we have examined a number of other substances, and in this communication we wish to direct attention to one of these in particular. This substance, 6-azauridine (2-ribofuranosyl-*as*-triazine-3,5(2*H*,4*H*)-dione) ('AzUR'), is so far the one which most closely approaches our aim of finding an oral agent which might control human pregnancy, with minimal toxic effects.

'AzUR' has been shown to be a highly active inhibitor of the growth of some species of bacteria[3], and of mammalian tumours, both in tissue culture[4,5] and *in vivo*[4,6]. It has also been found to be effective in leukæmia in man[7]. It is reported to have very low toxicity in mice[4,6,8] and in man[7,8], though it is somewhat toxic in dogs[4,8].

In our experiments, 'AzUR' was dissolved in water and given to mice by stomach tube in doses related to the weight of the animals. As in our previous work, we used Swiss albino mice. It has been reported that 'AzUR', because of its rapid rate of excretion, is more effective when given in divided doses[4]. In some of our experiments, therefore, we compared the effect of administering the substance in one single dose with that of administering it in three equal fractions of the daily dose at intervals of 8 hr.

Toxicity. The mildest sign of toxicity was a temporary fall in weight, which was rapidly regained when the 'AzUR' was withdrawn. More severe toxic effects were diarrhœa, a staring coat and death.

In non-pregnant animals, we have found that single doses of 0·5 mgm./gm., given for 9 consecutive days, were without effect in mature animals. In weanling animals, the same dose produced a significant but temporary loss in weight. Neither the younger nor the older mice showed any impairment of fertility when they were afterwards mated, and they produced normal litters. Thus, 'AzUR' does not appear to affect unfertilized ova.

In pregnant animals, the occurrence of toxicity depended on the size of the daily dose of 'AzUR', the number of days during which it was given, whether it was given as a single dose or in divided doses, and the stage of pregnancy. A single dose of 4 mgm./gm., given on the fourth day of pregnancy, was without toxic effect. Three consecutive single doses given on the fourth, fifth and sixth days killed some animals at 4 mgm./gm., and caused loss of weight at 1 mgm./gm.

Because of these effects, most of our further work was carried out with doses of 0·5 mgm./gm. Single or divided doses at this level, given for 1–4 days, were non-toxic in the early stages of pregnancy. Given for three consecutive days on or after the tenth day of pregnancy, they led to the death of several of the mothers. We believe that this was secondary to the death of the large conceptus at these late stages of pregnancy (see below).

Effect on pregnancy. The effect on pregnancy, like the toxicity, also depended on the dose, the duration of administration, the state of pregnancy and whether the drug was given in one dose or in divided amounts.

The most regularly effective time of dosing was for three consecutive days from the second, third or fourth day of pregnancy. Thus, in single doses over three days from the fourth to sixth day of pregnancy, 1 mgm./gm. interrupted every pregnancy, whereas 0·5 mgm./gm. interrupted about 50 per cent of pregnancies. Given for four days (third to sixth) instead of three days, single doses of 0·5 mgm./gm. interrupted all pregnancies. In divided doses, however, 0·5 mgm./gm. a day was invariably effective in interrupting pregnancy when given for only three days.

'AzUR' was less effective in the very earliest stages of pregnancy, so that 0·5 mgm./gm. given daily in divided doses for the first three days after copulation interrupted only 9 out of 16 pregnancies. Again, the same dose of 'AzUR' interrupted only half the pregnancies when given from the tenth to twelfth day, and none when given from the fourteenth to sixteenth day. There was, however, an important difference in the litters born to mothers dosed early, or late, in pregnancy. Those born to mothers dosed early in pregnancy survived, and were apparently quite normal; they were able, for example, themselves to conceive and rear their own young. Those born to mothers dosed late in pregnancy were smaller in number, and most of the young died within two days of birth.

The time of termination of pregnancy was related to the dosing schedule. Thus, with single doses over four consecutive days, from the third to the sixth day, pregnancy was terminated between the ninth and fifteenth day with 1 mgm./gm., and between the fourteenth and eighteenth day with 0·5 mgm./gm. Fractional doses totalling 0·5 mgm./gm. daily produced even earlier termination, between the eighth and the ninth day.

'AzUR' thus appears to have a selective action upon the conceptus during part of its existence. At particular levels, it does not affect the mother. Nor does it exert its maximum ovicidal effect during the very earliest stages of pregnancy, though this may be due to inaccessibility of the ovum rather than to its insensitivity. Again, it gradually ceases to affect the conceptus during the later stages of pregnancy, until eventually it allows the birth of some live young. Nevertheless, the size of litter is reduced, and this, together with the absence of toxicity on the mother at other stages, makes us believe that the apparent toxicity in the late stages of pregnancy are due to the death of one or two fœtuses, which by then are quite large.

A great deal more work needs to be done with 'AzUR' before we can decide whether it might be of use in the control of human fertility. There are, however, already several features of the incomplete results so far obtained which provide a considerable incentive to pursue this work. First, at doses which interrupt pregnancy, 'AzUR' has no effect on the unfertilized ovum, nor—with one exception—on the mother. The exception is the ill-effects produced when 'AzUR' is given late in pregnancy. Secondly, young born from mothers which were inadequately dosed seem to be perfectly healthy, and are themselves capable in due course of producing and rearing normal young. This lessens the possibility that, if 'AzUR' were to be used in the control of human fertility, congenital malformations might be produced in young born through inadequate dosing. Thirdly, there is now considerable evidence that 'AzUR' has very low toxicity in man. Amounts equivalent to 0·3 mgm./gm. daily, given intravenously at intervals of 8 hr. over as long as four weeks, are said to have no toxic effect whatever[7,8].

We acknowledge the generosity of Messrs. Spofa of Prague and Messrs. E. R. Squibb and Sons, U.S.A., in giving us supplies of 'AzUR'.

L-Glutamine and the Growth of Embryonic Chick Tibiotarsi *In vitro*

IN 1955 [1] Kieny published an account of the amino-acid requirements of eight-day embryonic chick tibiæ cultivated on various simple mixtures of inorganic salts and amino-acids, including L-glutamic acid. She reported that although the addition of glutamine to the media caused some increase in the length of the bones they also lost weight. In a later paper[2], however, she concluded that the substance had no effect on the bones. Recently, Biggers, Gwatkin and Heyner[3] have described the growth of embryonic chick, rat and mouse tibiæ on a relatively simple medium (denoted *BGJb*), which does not contain L-glutamic acid. It has been demonstrated in simple total deficiency experiments that L-glutamine is essential for growth in all three species, whether the response is measured in terms of length, wet weight or dry weight.

Other workers[4] have shown recently that explants of chick-heart tissue do not require L-glutamine because they contain glutamine synthetase. This enzyme catalyses the irreversible reaction:

$$\text{L-glutamic acid} + \text{adenosine triphosphate} + \text{ammonia} \rightarrow \text{L-glutamine} + \text{adenosine diphosphate} + \text{phosphate}$$

If we assume that glutamine synthetase is present in embryonic chick bones, then it is possible to argue that sufficient L-glutamine was synthesized from L-glutamic acid in Kieny's experiments to produce a maximal response. If so, then the addition of more L-glutamine to the system would produce no further effect. One can also argue that it is likely that some L-glutamine was formed to a minor extent in our experiments[3] since L-glutamic acid can arise from glucose in embryonic chick bones[5].

In order to settle these questions, the responses of seven-day embryonic chick tibiotarsi to different concentrations of L-glutamine have been studied in the presence and absence of L-glutamic acid. A 2 × 3 factorial arrangement has been employed: 1, 5 and 25 mgm. per 100 ml. of L-glutamine, and 0 and 25 mgm. per 100 ml. of L-glutamic acid, incorporated in all six treatment combinations in medium *BGJb*. In a preliminary experiment the concentration-response line of L-glutamine was determined. The results showed that the response becomes maximal in the range of 8·75–17·5 mgm. per 100 ml. Thus the concentration of 25 mgm. per 100 ml. which has been employed for the upper level of L-glutamine in the factorial experiment is more than sufficient to elicit a maximum response.

The uniformity of the paired limbs from embryos has been exploited by comparing the effects of the six treatments in a balanced incomplete block design. The pairs of tibiotarsi from fifteen embryos were allotted at random to the fifteen combinations between the six treatments taking two at a time. The bones were cultivated, using the floating lens paper technique, at 37° C. for 6 days in an atmosphere of humidified 5 per cent carbon dioxide in air. The medium was renewed every second day. At the end of the experiment the length of the bones was determined. The analysis of variance was done after converting all the data to logarithms. Only the intra-block error was estimated, and the adjusted treatment sum of squares were partitioned using the methods described by Kramer and Bradley[6].

The adjusted means are shown in Table 1, together with the analysis of variance. It is obvious that there is a highly significant linear regression of log length on the log concentration of L-glutamine in the medium and that some response occurred with only 1 mgm. per ml. L-glutamine in the medium. Since the L-glutamic acid and the interaction mean squares are not significant, there is no evidence that L-glutamic acid affects the response in length of the bones to L-glutamine. Thus there is no evidence that L-gluta-

mic acid is a precursor of L-glutamine in embryonic chick tibiotarsi, for if synthesis of L-glutamine did occur, the two concentration-response lines would be expected to separate, particularly at the lower levels of L-glutamine. Whether this is because this tissue does not contain glutamine synthetase remains to be determined.

The results also indicate why Kieny failed to demonstrate an effect of glutamine. The concentration used by her was only 0·16 mgm. per 100 ml., which is right at the lower end of the concentration-response line.

Hence, it is clear that L-glutamine is essential for the elongation of embryonic chick tibiotarsi *in vitro*, and that it is unlikely that it is produced from L-glutamic acid by this tissue. The importance of this compound to the cartilaginous rudiment is scarcely surprising in view of its essential role in the synthesis of purines[7] and chondroitin sulphate[8].

Organization of Function in Trypanosome Flagella

SOME cilia and flagella beat in a complex three-dimensional manner, and, in addition, the angular velocity at the tip is greater than at the base. Presumably the bundle of fibrils which make up a cilium or flagellum contains both conducting and contractile elements[1]. Trypanosome flagella, in common with most flagella and cilia, have 9 peripheral and 2 central fibres[2].

Acridine derivatives are well known to produce photosensitivity in cells and tissues. In the presence of pure 2 : 8-diamino-N-methylacridinium chloride (acriflavine) trypanosomes respond to light of wavelength 430–465 mμ first by an increased motility, secondly, by a stiffening of the flagellum which soon stops moving, and thirdly, by loss of refractility of the whole organism. To localize the site of photosensitivity a system of illumination was organized so that there was a circle of bright light about 4μ diameter and a background illumination of subdued red light to enable the operator to see a trypanosome throughout exposure without causing any additional damage.

The apparatus consisted of a microscope set up for Köhler illumination using a 6-V. 30-watt tungsten lamp. A ×40 objective (N.A. = 0·70) was used in place of the standard substage condenser and the trypanosomes were viewed through a ×80 oil immersion objective. An additional diaphragm held in a micromanipulator was placed close to the lamp house. This diaphragm consisted of an unprotected deep red gelatine filter (Wratten No. 70) which was carefully pierced with a pin from either side. The hole measured about 400μ in diameter. The image of this hole was formed in the plane of the object and was 4μ in diameter. A small circle of the same gelatine filter inserted into the eyepiece enabled the operator to observe both the trypanosome and the circle of light throughout an experiment.

Trypanosoma gambiense (an old laboratory strain) and *T. rhodesiense* (a newly isolated strain) were used in this experiment. The organisms were obtained from rat blood by centrifugation and diluted with a buffered-glucose Ringer's solution (pH 7·2) to give a count of about 12,000/μl. The final concentration of acriflavine was $10^{-5·1}$ M for *T. gambiense* and $10^{-4·81}$ M for *T. rhodesiense*; these concentrations were known from previous experiments to give complete immobilization in only a few seconds when the whole organism was illuminated. The movement of *T. rhodesiense* was reduced by the addition of 25 per cent of dextràn powder (Benger, Ltd.) to the diluting medium. The temperature of incubation and exposure was about 20° C. No difference in behaviour was observed between the two species of trypanosome. The combined results are expressed in Table 1.

The circle of light was localized in one or more of the four regions A, B, C and D as indicated in Fig. 1.

When the circle of light was brought to bear on a trypanosome, increased motility was first observed. Continued exposure of any part of the flagellum produced a slowing of that part and movement usually ceased after 30–40 sec. (see Table 1). Exposure

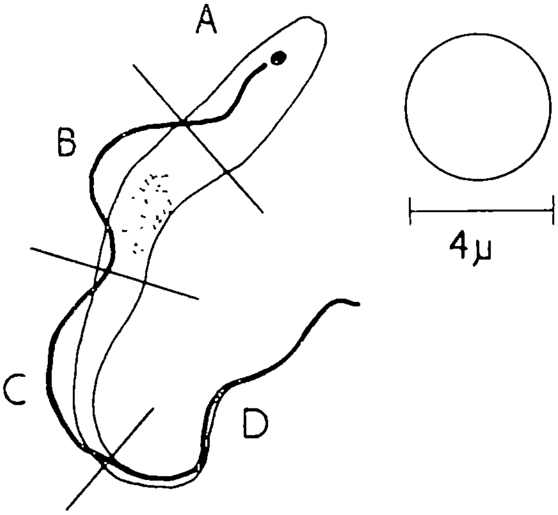

Fig. 1. Regions *A*, *B*, *C* and *D* of a trypanosome which were exposed to bright light. The circle, representing the area illuminated, is drawn to the same scale

for 1 min. of region *A* caused little obvious effect. Close examination after exposure revealed that the flagellum in this region neither accepted nor initiated any waves of contraction as it had done previously. Further exposure of region *A* caused sudden cessation of all movement of the flagellum and rapid loss of refractility of the organism. The time from full motility to this apparent state of death was less than 15 sec. in all cases. The total time taken for exposure of the region *A* to cause death was between 2 and 3 min. As the cone of light coming to a focus made an angle of 28° to the optic axis these longer exposures might have caused damage to other parts of the trypanosomes moving in and out of the cones of light above and below the focus. Exposure of the flagellum ($C + D$, group 5) for more than 3 min. showed that the action was specific to region *A*.

These findings can be summarized: In the presence of acriflavine, light on any part of the flagellum causes that part to stop moving, while the remainder of the flagellum continues to undulate. A similar quantity of light has no observable effect on the kinetoplast, but prolonged exposure of the kinetoplast results in death of the trypanosome.

As a rule, locomotion of trypanosomes occurs with the flagellum leading. A conducting element is therefore postulated to initiate waves of contraction that pass from the tip of the flagellum to the cell body. Groups 3 and 6 show that the flagellum behaves as though either a conducting element functions through the region of an injured contractile element or that contractions have local and self-initiated origins. In view of the cessation of all movement after prolonged exposure of the kinetoplast and of the complex screw-like waves which characterize flagellum movement in trypanosomes, it is suggested that contraction may be co-ordinated by information from the kinetoplast.

The observations qualitatively support the assumption made by Bradfield[1] that conducting and contractile elements are present in a flagellum. No evidence is provided on the mechanism of transmission of information along a flagellum, nor is it yet possible to localize, within the fibre bundle, these functional elements of conduction or contraction.

I am indebted to Dr. F. Hawking for encouragement and suggestions and to Dr. A. C. Allison and to Mr. M. Young for helpful criticism.

RADIOBIOLOGY

Fatty Acid and Glucose Metabolism in the Perfused Heart

Previous work on intact animals in which arteriovenous differences across the myocardium were measured[1,2] have suggested that fatty acids are an important metabolite for the heart. No work has been reported on the isolated heart with radioisotopes which allow a separation of the uptake and fate of a particular substrate. This communication gives an account of the uptake and certain metabolic fates of fatty acid and glucose in the isolated, perfused heart. The results indicate the readiness with which the myocardium utilizes both glucose and fatty acids, and suggest that fatty acids are preferentially oxidized. The latter observation provides a possible explanation for the puzzling increase in cardiac glycogen known to occur with fasting or with untreated diabetes.

The isolated perfused rat heart described by Bleehen and Fisher[3] was used. This was modified as indicated by Morgan and Park[4] to permit the use of a low circulating volume. To measure formation of carbon dioxide labelled with carbon-14 from labelled substrates, a closed system was developed which included 15 ml. of Krebs–Henseleit bicarbonate solution and about 100 ml. of a gas mixture (95 per cent oxygen : 5 per cent carbon dioxide). Glucose (5 m*M*) and free fatty acid (0·4 m*M*) concentrations were within the physiological range for the rat. A 0·5 per cent solution of dialysed human serum albumin was used in experiments with free fatty acids. Male albino rats weighing 200–240 gm. were killed by decapitation after an overnight fast. No anticoagulant was used. Hearts were perfused with a substrate-free Krebs–Henseleit solution for 5 min., during which time the coronary flow, force, and rate of contraction became stable. Perfusion for 30 min. in the closed system followed. Then the hearts were weighed and digested in 30 per cent potassium hydroxide. Non-saponified lipids were removed by a single petroleum ether extraction. Following acidification to *p*H 1, tissue fatty acids were recovered by three petroleum ether extractions. Analyses for glucose, glycogen and for incorporation of carbon-14 into carbon dioxide, glycogen and fatty acids were essentially the same as described by Winegrad and Renold[5] for adipose tissue. Lactate was measured enzymatically[6] and free fatty acids by Gordon's method[7].

A summary of results is shown in Table 1. It will be seen that free fatty acids (0·4 m*M*), when present as the only substrate, are readily removed by the heart. When the fatty acids were labelled with palmitate-1-^{14}C nearly half the uptake was found in carbon dioxide. Palmitate label was also recovered to a significant extent in 'tissue fatty acids'; whether

Table 1. UPTAKE AND FATE OF GLUCOSE-U-^{14}C (5 mM) AND PALMITIC ACID-1-^{14}C (0·4 mM) IN PERFUSED RAT HEART

All perfusions were for 30 min. Uptake, lactate production and label in CO$_2$, glycogen and tissue fatty acids (TFA) are expressed as μM/gm. wet weight/30 min.; residual glycogen as μM-glucose/gm. wet weight. Per cent = fraction of uptake.

FFA = free fatty acid (= unesterified = non-esterified fatty acid).

* ^{14}C labelled substrate.

† S.E. of mean.

‡ Sum of CO$_2$, glycogen and lactate (corrected for glycolysis during perfusion: in separate hearts the glycogen content after 5 min. perfusion with Krebs–Henseleit solution was 18·3 ± 1·2μM glucose/gm. wet weight) divided by uptake of glucose.

these represent fatty acids present in the tissue as free fatty acids or incorporation into triglyceride or other complex lipids has not been determined. Addition of unlabelled glucose (5 mM) to the perfusate had no effect on the uptake of free fatty acids; furthermore, the fraction of label from palmitate-1-^{14}C appearing in carbon dioxide and in tissue fatty acid was unchanged.

With glucose-u-^{14}C (5 mM) as the only substrate, 17 per cent of the uptake appeared as $^{14}CO_2$. There was definite incorporation of label into glycogen; essentially none was recovered as tissue fatty acid. Lactate production could account for 56 per cent of the glucose uptake and glycogen breakdown (Table 1). Addition of unlabelled free fatty acids (0·4 mM) strikingly reduced glucose oxidation to carbon dioxide. Under these conditions the uptake of glucose was slightly less, more residual glycogen was found after perfusion and more glucose carbon label was recovered in glycogen. No change in lactate production was observed.

The marked inhibition that free fatty acids exert on glucose oxidation to carbon dioxide suggests that fatty acids are preferentially oxidized when both substrates are present in the stated concentrations. It is unlikely that the reduced glucose oxidation to carbon dioxide produced by the addition of free fatty acids represents simply dilution of labelled carbon dioxide precursors by unlabelled substrate, since the addition of unlabelled glucose could not similarly alter the oxidation of palmitate-1-^{14}C. Furthermore, during free fatty acid inhibition of glucose oxidation, more of the glucose-u-^{14}C is incorporated into glycogen and the total myocardial glycogen is slightly increased. This suggests that the simultaneous presence of free fatty acids had diverted more glucose to glycogen synthesis with a net 'sparing' of cardiac glycogen.

Since fasting and untreated diabetes mellitus results in the mobilization of free fatty acids from adipose tissue these findings may explain the paradoxical observations that cardiac glycogen increases with fasting[7] and with untreated diabetes[8] in contrast to the depletion of glycogen in liver and diaphragm[9].

We wish to thank Prof. R. B. Fisher and Sir Hans Krebs for continued interest and especially for help to one of us (J. C. S.) during tenure of a U.S. Public Health Service fellowship in the Department of Biochemistry, University of Oxford, 1958–59. This work was supported in part by the Boston Medical Foundation, Inc., the Massachusetts Heart Association, and the U.S. Public Health Service. One of us (L. H. O.) was supported by the Samuel A. Levine Fellowship in Cardiology of the Massachusetts Heart Association and a Welcome Trust travelling fellowship.

HÆMATOLOGY

Site of Binding of Chromium-51 to Hæmoglobin

Gray and Sterling[1] have shown that when red blood cells are incubated with sodium chromate labelled with chromium-51, the latter enters the red cell and becomes firmly attached to intra-erythrocytic hæmoglobin. This tagging became the basis for *in vivo* studies of red cell volume and estimations of red cell life-span[2,3]. Despite its wide application in clinical medicine, little is known of the actual hæmoglobin-chromium-51 binding mechanism or site.

The molecule of normal adult hæmoglobin (A) has been shown to contain two pairs of distinguishable polypeptide chains (α and β) and can be schematically designated as $\alpha_2\beta_2$ (ref. 4). Most of the important abnormal hæmoglobins are altered only in the β chains. For example, hæmoglobin C can be represented as $\alpha_2\beta_2{}^C$ (ref. 5). Hæmoglobin H, an electrophoretically 'fast' variant, however, contains no α-chains and has been designated as β_4 (ref. 6). In acid solutions the hæmoglobin molecule undergoes asymmetric dissociation into free α_2- and β_2-units which

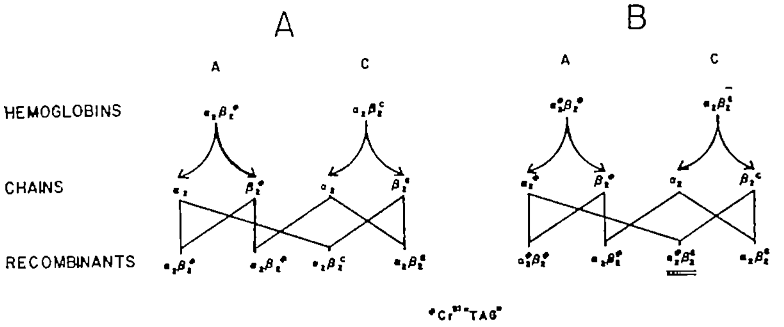

Fig. 1

recombine randomly when the solution is returned to neutral *p*H [7]. These facts have been utilized in this work in an attempt to elucidate possible sites of binding of chromium-51 to hæmoglobin.

Red cells from a patient with hæmoglobin *H* disease were tagged with iron-59 and chromium-51 as part of erythrokinetic studies. Hæmoglobin solutions were made by hæmolysis with toluene and cleared by ultracentrifugation. Oxyhæmoglobins *H* and *A* were separated by starch-block electrophoresis in phosphate buffer *p*H 7·0 in a 3-hr. run at 50 m.amp. and 400 V. The separated components were then analysed for hæmoglobin content and for chromium-51 and iron-59 activity by γ-ray spectrometry in a sodium iodide well-type scintillation counter. Results are presented in Table 1.

Table 1

	Per cent of total hæmoglobin	c.c./min. ^{59}Fe	Per cent of total ^{59}Fe counts	c.c./min. ^{51}Cr	Per cent of total ^{51}Cr counts
Hæmoglobin *H*	18	16	20 5	1,107	33 7
Hæmoglobin *A*	82	62	79 5	2,178	66 3

This indicates that the chromium-51 activity of hæmoglobin *H* (β_4) is approximately twice that of equivalent amounts of hæmoglobin *A* ($\alpha_2\beta_2$).

One explanation for the differences in chromium-51 activities of hæmoglobin *H* and *A* would be that chromium-51 tags primarily to β-chains. To test this hypothesis, recombination experiments with chromium-51-labelled hæmoglobin *A* and non-radioactive hæmoglobin *C* were performed.

If chromium-51 binds only to β chains no radioactive hæmoglobin *C* would be seen after recombination, since no 'hybrids' would be formed (Fig. 1*A*). On the other hand, if chromium-51 becomes attached non-specifically to both α- and β-chains, radioactive hæmoglobin *C* would result, due to 'hybridization' (Fig. 1*B*).

Red cells from a normal person were labelled with chromium-51 and hæmolysed immediately. Hæmoglobin *C* was obtained from the hæmolysate of a patient with homozygous hæmoglobin *C* disease. Equal amounts of these solutions were mixed and then divided into control and reaction portions. Hæmoglobin concentration of these was approximately 5·0 gm. per cent. The reaction portion was dialysed for 12 hr. against acetate buffer *p*H 4·7 and then returned to basic *p*H by successive dialysis against distilled water and barbital buffer *p*H 8·6. A precipitate was removed by high-speed centrifugation. Both control and reaction mixtures were converted to cyanmethæmoglobin and separated by starch-block electrophoresis in barbital buffer at *p*H 8·6 in a 16-hr. run at 48 m.amp. and 350 V. The fractions were then eluted and analysed for hæmoglobin concentration and chromium-51 activity. Results are listed in Table 2.

Table 2

	Per cent hæmoglobin		c.c./min. ^{51}Cr		Per cent ^{51}Cr activity	
	A	*C*	*A*	*C*	*A*	*C*
Control mixture	39 3	60·7	955	38	96·2	3 8
Reaction mixture	42 5	57 5	4,069	226	94·6	5 6

Similar results were obtained in experiments using hæmoglobin *S* and agar electrophoresis. The reason for the chromium-51 activity in the hæmoglobin *C* fraction is uncertain. Approximately 3 per cent can be accounted for by hæmoglobin A_2 present in the *A* hæmolysate and tagged along with hæmoglobin *A* (unpublished observations).

Using two different experimental approaches, it has been shown that chromium-51 is attached to hæmoglobin largely on the β-chains. Since the chromium-51 tag remains with the β-chain during dissociation and recombination, this may provide a useful tool for localizing altered polypeptide chains of abnormal hæmoglobins.

IMMUNOLOGY

Characteristics of γ-Globulin, lacking Antibody Properties, in New-born Pigs

IN solving the problem whether γ-globulin lacking antibody properties exists and whether γ-globulin can be formed without an antigenic stimulus, our attention was focused on γ-globulin in piglets which had not been fed with colostrum[1]. The serum of piglets bred by a special technique without colostrum[2] is very suitable material for these experiments, because the placenta of these animals does not permit the penetration of γ-globulin[3], and the new-born animals lack this protein completely[4-6]. In our previous experiments[1], however, the presence of a detectable amount of γ-globulin has been demonstrated after 100 times concentration of the γ-globulin fraction of the serum taken from the piglets bred under sterile conditions without colostrum for the first 14 days after birth; at that time piglets are not yet able to produce antibodies, not even against an artificially injected antigen (*Brucella suis*) nor against antigens naturally present (*E. coli* strains). This γ-globulin cannot combine with any of the tested antigens and it could therefore be described as 'normal' γ-globulin. By injecting methionine labelled with sulphur-35 to piglets bred without colostrum it was found that this small amount of γ-globulin was not transmitted passively from the mother by the intra-uterine route, but that the γ-globulin of the young animals was synthesized *de novo* during the period when the piglets were not yet producing antibodies.

In the present communication the results of physicochemical and immunochemical investigations of γ-globulin of piglets which were bled shortly after birth without the intake of colostrum are presented. The γ-globulin was isolated from the serum by twice-repeated preparative electrophoresis on a starch block in veronal buffer, *p*H 8·6, $\Gamma/2 = 0{\cdot}05$. The yield of the product which we called γ_N (γ-globulin neonatorum) was 50–80 μgm. from 1 ml. of the serum. Paper and agar electrophoresis revealed a microheterogeneity typical of γ-globulins. The admixture of β-globulin was not detectable by paper and agar electrophoresis; its presence was demonstrated only using immunoelectrophoresis. Ultracentrifugation analysis indicates that the preparation γ_N contains a large component, apparently of a microheterogeneous nature, with a mean corrected sedimentation coefficient $S_{20,w} = 3{\cdot}1\ S$, and a small component with a sedimentation coefficient $S_{20,w} = 6{\cdot}1\ S$, contrary to the γ-globulin of adult pigs, which contains only components of 6·7 *S* and 18 *S*. The preparation was subjected to chromatography on *DEAE* cellulose in phosphate buffer, *p*H 8·0, with an ionic strength gradient according to Fahey[9]. The distribution of the proteins in the fractions is shown in Fig. 1. In order to carry out the immunochemical analysis of the separated fractions, two rabbit antisera were prepared. The first one was obtained by immunization of rabbits with electrophoretically prepared γ_2-globulin of adult pigs and was called anti-*P*γ*GA*. The second one (anti-*PGN*) was obtained by immunization of rabbits with a fraction isolated by starch block electrophoresis from the γ-globulin area of new-born pig serum and containing γ- and β-globulins. Each chromatographic fraction was subjected to the agar precipitation test in Preer's modification. The precipitate with anti-*P*γ*GA* serum appeared in fractions 13–30. This was a guide for making a sub-fraction $\gamma_{N'}$ which contained non-precipitating protein from the large frontal peak (about 50 per cent of protein γ_N) and $\gamma_{N''}$ containing protein precipitating with anti-*P*γ*GA* (about 20 per cent protein γ_N). The sedimentation coefficient $S_{20,w}$ was 2·7 *S* for $\gamma_{N'}$ and 5·1 for $\gamma_{N''}$. If $\gamma_{N'}$ is precipitated in immunoelectrophoresis with antiserum against piglet β- and γ-globulin (anti-*PGN*) at least four different components appear. Anti-*P*γ*GA*, similarly as in Preer's modification, does not form any precipitate with $\gamma_{N'}$ in immunoelectrophoresis. That means that no antigenic determinant of $\gamma_{N'}$ is identical with γ-globulin of adult animals. $\gamma_{N''}$ precipitates in a single line with either of the antisera used. Anti-*PGN* precipitates also with adult γ_2-globulin, showing a double precipitation line. This is further evidence that serum of new-born pigs contains proteins which possess at least some determinants of γ-globulin.

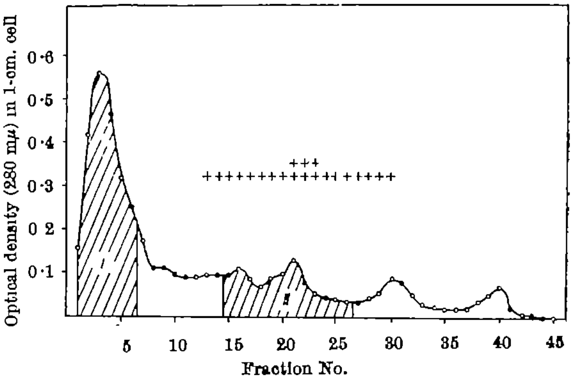

Fig. 1. Chromatography of γ_N on *DEAE* cellulose. Weight of protein, 25 mgm. Gradient from 0 02 *M* sodium phosphate, *p*H 8·0, to 0·3 *M* sodium phosphate, *p*H 8·0. Fractions in which precipitate with anti-*P*γ*GA* serum was formed are expressed by crosses

To elucidate completely the antigenic nature of γ_N and its relationship to γ_2 of adult animals a quantitative precipitation of anti-*P*γ*GA* serum with antigens $\gamma_{N''}$ and γ_2 was carried out. The results of the precipitation in Fig. 2 show the sharp peak, contrary to the high and broad zone of maximal precipitation with $\gamma_{N''}$. Although we cannot rule out that the preparation of $\gamma_{N''}$ contains protein which does not participate in the precipitation with anti-*P*γ*GA* (for example, an admixture of β-globulin) the precipitation curves indicate quite clearly that $\gamma_{N''}$ is not fully identical with γ_2. If this were the case, both precipitation curves would fuse or have the same shape and be shifted on the antigen axis in the co-ordinate system used in Fig. 2. Since $\gamma_{N'}$, which contains the components with the smallest sedimentation coefficients from the whole mixture, does not precipitate at all with anti-*P*γ*GA*, it was investigated whether its possible antigenic relationship with γ-globulin will manifest itself by inhibition in the precipitation of anti-*P*γ*GA* with γ_2 in the presence of excess of $\gamma_{N'}$. In this test, $\gamma_{N'}$ behaved as a quite indifferent protein, and there is thus no evidence of its immuno-chemical relationship with γ-globulin.

Immunochemical data, together with the sedimentation and electrophoretic characteristic, thus indicate

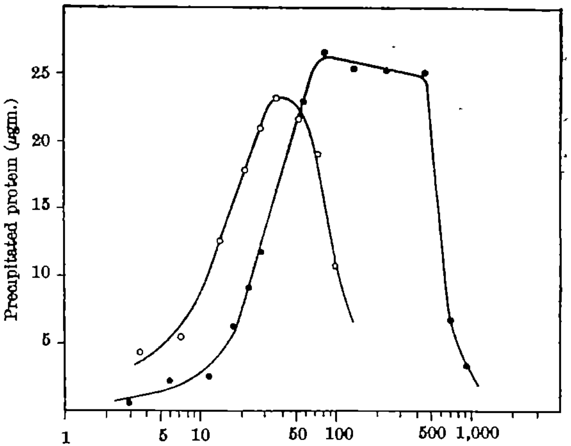

Fig. 2. Precipitation curves of anti-*P*γ*GA* serum versus adult γ_2-globulin (open circles) and $\gamma_{N''}$ protein (solid circles)

that the serum protein of new-born pigs which is electrophoretically identical with γ-globulin contains components in close antigenic relation with γ-globulin of adult animals but immunochemically not identical. These components differ from γ-globulins of adult animals also by their molecular weight as shown by determination of a significantly lower sedimentation coefficient.

Effect of some Metabolic Inhibitors on Antibody Formation

Recently the use of metabolic inhibitors, particularly analogues of nucleic acid components, has been proving an effective tool for investigating the processes involved in antibody formation[1-8]. The direct determination of the metabolic changes attendant on these processes is practically impossible at the present stage. After the first immunizing dose, only a very small proportion (about 1 per cent) of the lymphoid cells isolated from the spleen or the lymph nodes is active in antibody formation. The detection of any biochemical changes in these cells is made exceedingly difficult not only by the large 'background' of inactive cells (99 per cent) but also by the absence of serologically demonstrable antibody from the active cells in the initial (inductive) phase. Earlier I showed that the nucleic acid antimetabolite 6-mercaptopurine acts only during this inductive phase, but does not affect antibody production if administered during the productive phase[9]. If, then, antibody formation is inhibited by means of suitable agents without affecting protein synthesis in general, we may with some degree of plausibility draw conclusions about the processes taking place in the inductive phase.

The work to be described here, in which the effect of a variety of inhibitors was examined, was intended chiefly to show whether these inhibitors act directly by interference with intracellular metabolism, or rather indirectly through the inhibition of mitotic cell division resulting from their primary action. If it were possible to show that the inhibition of antibody formation is directly connected with the reduction of mitotic activity then this would constitute evidence for the validity of the clonal selection theory at the cellular level. A further objective of this work was, of course, the hope of finding compounds more effective in suppressing immunological response and less toxic than 6-mercaptopurine.

Table 1. Action of Metabolic Inhibitors on Antibody Formation

Type of inhibitors	Compound	Dose (mgm./100 gm. body-weight)	Inhibition of antibody formation
Pyrimidine antagonists	5-Fluorouracil	2·0*	0
		1·0	0
		0·5	0
	5-Bromouracil	5·0	0
	6-Azauracil	2·0	0
		1·0	0
		0·5	0
	6-Azauridine	500·0*	+
		50·0	±
		5·0	0
	6-Azauridine-monophosphate	4·0	0
	2-Thiouracil	5·0	0
		10·0	0
	4-Methyl-2-thiouracil	1·0	0
		5·0	0
	6-Azathymine	0·5	±
	2-Thio-6-azathymine	2·0	0
	2-Thiothymine	2·0	0
Purine antagonists	6-Mercaptopurine	0·5*	+
		0·3	+
	8-Azaguanine	1·0	±
		0·5	0
	6-Thioguanine	0·1*	+
		0·05	+
Folic acid antagonist	Aminopterine	0·3	+
		0·15	+
		0·05	±
Inhibitors of mitotic division	Colchicine	0·3*	0
		0·2	0
	Demecolcine	0·1	0
	Actinomycin *C*	0·003*	0
Amino-acid antagonist	DL-Ethionine	5·0	0
Polyfunctional alkylating agents	*TS*-160 (trichlorethylamine)	0·1	0
	Myleran	2·0*	+
		0·5	0
	Leukeran	0·5	0

0, No significant inhibition of antibody formation; ±, inhibition significant in some animals; +, total inhibition in all cases.

*, Dose causing distinct toxic effects for the recipients of the spleen cells—new-born rabbits.

Inhibitory activity was determined by the same method as had been used in previous work with 6-mercaptopurine[9]. The cells isolated from the spleen of a normal non-immunized donor were mixed *in vitro* with *Brucella suis* antigen and injected intraperitoneally in a dose of 50 × 10^6 cells into three- to five-day-old rabbits. The antibodies produced by the transferred cells reach their highest titre 5–7 days after transfer, that is, at that stage in the development of the recipient when the latter is still incapable of responding to the antigen injected by antibody formation[10]. The evaluation of antibody response and its inhibition was confined to that stage (that is, the tenth to twelfth day of life of the recipients). The inhibitors were injected daily, for five days after transfer of the cells, at various dose-levels as indicated in Table 1 (only doses which were not yet fully toxic for the animal are recorded). In all, 400 neonatal rabbits were used in these experiments. The use of neonatal animals, which are more sensitive to the action of inhibitors[11], made it possible to distinguish more precisely between the general cytostatic effect of the inhibitors and their selective action on antibody formation.

The inhibitors used included some analogues of the purine and pyrimidine bases, of folic acid, and of methionine, as well as some known cytostatics and polyfunctional alkylating agents. Table 1 summarizes the effects of some of these compounds. Inhibitory activity is found predominantly among the purine derivatives, whereas the pyrimidine derivatives do not inhibit antibody production. 5-Fluorouracil had no effect on antibody production at doses which are known to be carcinostatic[12] and which were toxic for the neonatal rabbits. The only active pyrimidine antagonist was 6-azauridine (kindly supplied by Dr. J. Škoda, of the Institute of Organic Chemistry and Biochemistry of the Czechoslovak Academy of Science; cf. ref. 13), but only in large, toxic doses (500 mgm./100 gm. body-weight). Since, of the purine analogues, the sulphur-substituted compounds were the most active, I also investigated a number of thio-compounds based on the pyrimidine skeleton (the compounds were kindly supplied by Dr. J. Gut, of the same Institute; cf. ref. 14); but the introduction of sulphur into the molecules did not lead to any enhancement of the activity.

The action of compounds known to inhibit cell division gave further information relevant to the question whether the formation of a cell clone is a pre-requisite for the induction of an antibody reaction. Injection of colchicine and actinomycin *C* in the highest possible doses was found not to affect the antibody response. These results accord with those obtained with 5-fluorouracil, which was also inactive in inhibiting antibody formation in doses which were generally cytotoxic.

Since other experiments have also indicated that the essence of the inductive phase does not lie in the multiplication of a predetermined type of cells under exposure to the antigen[15], it may be concluded that the effect of the active purine analogues on antibody formation involves direct interference with the adaptive metabolic processes which take place during the inductive phase.

PATHOLOGY

Tissue Responses to Filter Membranes of Various Porosities

In the course of work on experimental silicosis in which diffusion chambers were used, it was discovered that the reaction of the tissues to the chamber varied greatly with the pore-size of the membrane of which its walls were made. The chambers were of the type used in earlier experiments[1] and the membrane was 'Millipore' type. The porosities tested were 0·65μ, 0·8μ, 1·2μ, 3μ and 5μ.

When placed within the rat's peritoneal cavity, each chamber is covered with mast cells and polymorphs within an hour. The mast cells rapidly disrupt and the granules enter the pores of the membrane; wherever the pores are full of 'cement', however, these cells remain intact. Within the next few hours large numbers of polymorphs enter the pores of the membrane, but comparatively few succeed in reaching the lumen of the chamber; most of them undergo rapid dissolution in the pores. Simultaneously, an inflammatory reaction develops in the adherent tissue which gradually increases until it is most intense after about three days. Thereafter, a fibrous reaction gradually develops so that, after 14 days, a dense fibrous capsule encloses the chamber. Half-chambers excite the same response as whole chambers (Figs. 1 and 2). The inflammatory reaction is most acute with membranes of 1·2μ, 3μ or 5μ porosity. With 0·8μ-pore membrane, however, the reaction is less acute: fewer polymorphs enter the pores and die there; no intact polymorphs reach the lumen of the chamber; the inflammatory reaction in the adherent tissue is less, and the fibrous capsule that forms is thinner. With 0·65μ-pore membrane, the majority of chambers do not even adhere to the omentum or mesentery: only a small number of polymorphs manage to enter the pores and, consequently, only a small amount of nuclear debris collects in the pores; the fibrous capsule is quite delicate.

Soaking the filter membrane in various solvents fails to make it less inflammatory. The only way to make it non-irritant to the tissues is to block the pores, either with 'cement' or by softening the membrane with acetone. In any event, the membrane is not toxic to cultures of *Strept. pyogenes*. There is no evidence therefore for the presence of a toxic contaminant.

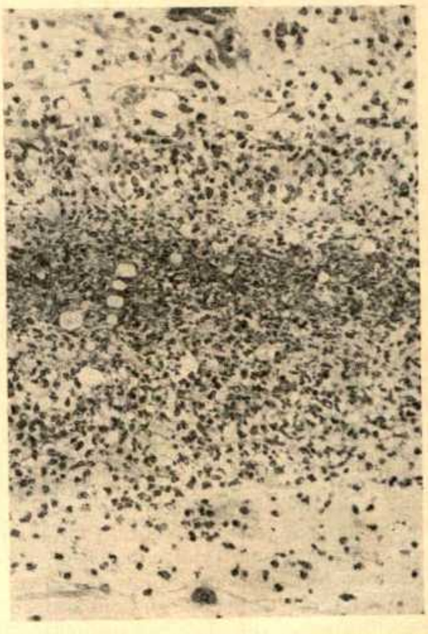

Fig. 1. Half-chamber made with 1·2μ-pore membrane after 2 days intraperitoneally. The membrane runs across the centre but is buried in inflammatory exudate. It is represented by the dark-staining band, which consists of the debris of polymorph nuclei within its pores. Inflammatory exudate covers both surfaces. (Hæmatoxylin and eosin. × 100)

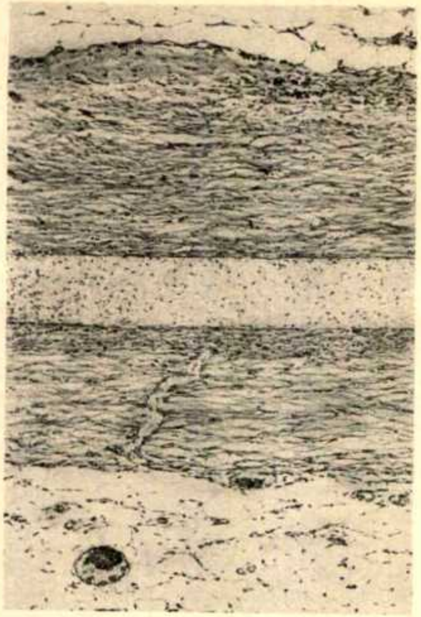

Fig. 2. Half-chamber made with 1·2μ-pore membrane after 14 days intraperitoneally. The membrane (centre) is now enclosed by a dense mass of fibrous tissue. Its pores contain only a few polymorphs. (Hæmatoxylin and eosin. × 65)

This acute inflammatory and fibrotic reaction was unexpected, because earlier experiments[1,2] showed that chambers made with 0·1μ-pore (or even 0·45μ-pore) 'Millipore' membrane did not adhere to tissues or excite an inflammatory reaction ; and all 'Millipore' filters have the same chemical composition and the same weight of cellulose ester for a given size of filter, the only variable being the pore size. Since it seems that the intensity of the inflammatory reaction correlates with the ease with which polymorphs can enter the pores and die therein, the membranes may produce their effect by acting as a polymorph 'trap'. Clearly, if the dying polymorphs released an 'inflammatory' agent in the form of a vascular permeability-increasing factor, an inflammatory reaction would build up rapidly. This would be terminated only when fibrous tissue had sealed off the pores. On the other hand, there is the possibility that the migration and death of the polymorphs is secondary and merely one aspect of an acute inflammatory response initiated in some other way by the membrane. Permeability factors are becoming embarrassingly numerous and can be readily activated ; for example, contact of serum with diethylaminoethyl cellulose during chromatography is sufficient to release one[3]. But, if the membranes are showing surface activity and releasing a permeability factor from the tissue fluids, it is difficult to explain why only the coarser-pore membranes do so, since, presumably, they expose a much smaller surface area to the tissue fluids than do membranes with finer pores (less than 0·45μ). Whatever the mechanism, it is interesting to find a chemically pure and 'inert' material capable of causing an acute inflammatory response and subsequent fibrosis because of a slight alteration in its physical form.

The significance of the mast cell response is difficult to assess. It was not caused by trauma, because these cells were intact over the 'cement-filled' areas. Since they do not react to smaller-pore (0·45μ or less) membranes, it is tempting to link them with the initiation of the inflammatory reaction ; and, of course, they are well equipped to do so, since they contain histamine as well as serotonin and heparin. However, there is little other evidence to link mast cells with acute inflammation.

If disintegrating leucocytes could release a permeability factor, it would have a bearing on the problem primarily under consideration in these experiments, namely, how silica induces fibrosis. Little is known about the chemical mediators in chronic inflammation and fibrous repair, but it seems reasonable to assume that both processes are essentially manifestations of the sustained release in the tissues of a permeability factor. Such a factor would maintain a steady flow of fibroblasts and leucocytes from patent capillaries until sufficient fibrous tissue has formed to wall off the irritant. On this basis silica dust might be unique, not in its influence on fibroblasts, as is often assumed, but only in its ability to persist in the tissues and disintegrate the leucocytes which ingest it.

A more detailed account of this work will be published[4].

BIOLOGY

Proposed Revisions of 'Transplantese'

The jargon employed by students of tissue transplantation has been named 'transplantese' by one of us[1].

Within a given species we wish to distinguish grafts exchanged between genetically identical individuals from those between genetically diverse individuals. Snell[2] suggested the word 'isograft' for the former and 'homoio-transplant' for the latter. Many people have remarked on the confusion arising from the use of isograft, which connotes genetic or antigenic uniformity, and 'isoantigen', which connotes the reverse. The latter is by far the older term and widely used by immunologists. As has been pointed out previously, transplantation immunity is but one facet of immunology, and a minority should try to conform to the terminology employed by the majority. There is also a more serious consideration which has been overlooked. The word 'isos' means 'equal', and 'homos' and 'homoios' mean 'the same'. It is therefore not logical to make the prefix 'iso-' denote a greater degree of similarity than 'homo-' or 'homoio-'.

Grafts between species are of less general interest. They have been called xenografts or heterografts.

Three adjectives related to the above nouns are in common use : 'isologous' (=genetically identical), 'homologous' (=of the same species, but not genetically identical) and heterologous (=of different species). Recently 'autologous' has disfigured the literature. This is not the place to discuss the origins and meaning of the termination '-logous', but it is not suitable for defining genetic relationships. 'Homologous' should always be used to denote some type of agreement or correspondence. There is no possible justification for using the word to mean 'genetically different' since it is a flagrant contradiction of its proper use. 'Isologous' has no popular meaning; but, for the reasons stated above, it should not be made to denote a closer similarity than 'homologous'. 'Heterologous' is the correct antithesis of 'homologous', but it has no necessary reference to inter-specific differences. Indeed immunologists often use 'homologous' and 'heterologous' without any genetic connotation. The 'homologous' antigen is generally that used for immunization, and another antigen, even if derived from the same individual as the former, could be described as heterologous. The terms are often so used in discussions concerned with synthetic antigens. 'Autologous' is both meaningless and unnecessary.

One of us[1] suggested 'isogenic', 'allogenic' and 'heterospecific' in place of 'isologous', 'homologous' and 'heterologous', and we should like to reconsider these terms here.

So far as we can discover 'isogenic' was originally used to denote a population that was homozygous for all genes. The meaning seems to have been tacitly extended to cover other types of genetically uniform populations such as monozygotic twins and the F_1 between inbred strains. This being so there can be no possible objection to the use proposed above. However, we feel there is a need for a synonym that avoids the prefix 'iso-'. This is particularly needed with tumours. It is notorious that in the past so-called tumour-specific antigens have turned out to be isoantigens. There are now several examples of intra-strain immunity to tumours and it is most unfortunate that authors such as Hirsch[3] have used 'isoimmunity' in this context. We suggest the introduction of 'syngeneic' as a synonym for 'isogenic'. If one does not wish to refer to 'intra-strain immunity' one could then use 'syngeneic immunity'.

No objections have been raised against 'allogenic' as written, but in conversation it can be confused with 'allergenic'. We therefore propose 'allogeneic'; this should be pronounced 'allogeneeic', but even if pronounced 'allojeenic' it should not sound like 'allergenic'.

'Hetero-specific' has been used before and cannot be said to be illogical; but it is a Greco-Latin hybrid and we feel that 'xenogeneic' goes well with the other two terms we have suggested and is perhaps preferable.

We see no reason for any modification of 'autograft'. The adjective 'autoplastic' has been in use many years, and it does not seem justifiable to abandon it. A tumour growing in its original host has long been spoken of as 'autochthonous'.

'Homograft' and its commonly used synonyms are too firmly established and too useful to abandon. It must be realized that the term should embrace all types of intra-specific grafts and cannot be reserved for grafts between genetically diverse individuals. We cannot say that 'isograft' has proved a very fortunate term. Snell[2] originally intended it as an abbreviation of 'isogenic graft' although very few people seem aware of the fact. The expanded form is certainly preferable to that generally used. 'Isogenic homograft' is more precise. For reasons given above we feel there is much to be said for the employment of 'syngeneic homograft or graft'. 'Allogeneic graft' could, and probably will, be abbreviated to 'allograft'; but recent experience does not encourage premature abbreviation.

Table 1. PROPOSED REVISIONS OF 'TRANSPLANTESE'

Nouns			Adjectives		
Old terms	Proposed new terms	Alternative new terms	Old terms	Proposed new terms	Alternative new terms
Autograft	Autograft	—	Autologous	Autoplastic autochthonous (acc. to context)	
Isograft	Syngeneic homograft or graft	Isogenic homograft or graft	Isologous	Syngeneic	Isogenic
Homograft (general sense)	Homograft	—	Homologous	Allogeneic	—
Homograft (connoting genetic diversity)	Allogeneic homograft or graft	—			
Heterograft	Xenograft	Heterospecific graft Interspecific graft Heterograft	Heterologous	Xenogeneic	Heterospecific Heterologous

'Heterograft' is a relatively inoffensive term; but the meanings of 'heteros' and 'allos' are similar and do not provide a suitable contrast. We feel that the old term 'xenograft' is more explicit. The proposed alterations are shown in Table 1.

We should like to see international agreement on the terms to be used in this interesting field of study; but we cannot see any justification for continuing to antithesize sameness and equality in the perverse way that has commonly been done.

Electrophoretic Patterns of Lymph Node Proteins in Hybrid F_1 Mice irradiated and treated with Myeloid and Lymphoid Cells from a Parental Strain

IT is generally admitted that graft antibodies do not circulate in the plasma and that graft immunity is carried on by cells from the lymphoid tissue and more precisely by those 'immunologically competent cells' of which the most striking features are their plasma cell-like morphological aspect and their high content of ribonucleic acid[1].

The purpose of this work was to find out whether graft immunization in lymph nodes will result in a modification of the electrophoretic pattern of the lymph node proteins as investigated by means of starch-gel electrophoresis[2]. It is implied that eventual modifications in patterns could correspond to the graft antibody located inside the immunized cells.

(*a*) In a first group of experiments, we have studied the lymph nodes of the host in connexion with a graft of lung tissue. The nodes were removed 5–7 days after insertion of the graft. Genetically the systems used herein were as follows: Host: *C57Bl6*; donors: *DBA2*. Hosts: *DBA2*; donors *C57Bl6*. Hosts: *C57Bl6*; donors $(C57Bl6.\ DBA2)F_1$.

In all these cases the lymph node content in hyperbasophilic cells was moderately increased, up to 4 and 6 per cent. The electrophoretic patterns of the lymph node proteins were apparently similar to those of lymph nodes from non-grafted mice, *C57Bl6* or *DBA2* or F_1 taken as controls and also to those of mice grafted with isogenic lung grafts. In the latter the number of cells with hyperbasophilic cytoplasma was normal.

(*b*) In a second group of experiments, we have studied the lymph node proteins of $(C57Bl6.DBA2)F_1$ receiving a whole-body irradiation of 500 rads (200 kV., 50 cm. distance, 12 m.amp., 0·5 aluminium, 0·5 copper) and injected 24 hr. later with 2×10^7 bone marrow cells and 2×10^7 lymph node cells from the parental strain *C57Bl6*.

In this group, we actually observed in the lymph nodes a definite reaction of immunologically competent grafted cells against the antigens of the host. The number of hyperbasophilic cytoplasm cells seven days after grafting was considerable, reaching a percentage of more than 40 (ref. 3). When extracts of these lymph nodes were submitted to electrophoresis through starch gel, an extra band (Fig. 1) appeared which does not exist in extracts of lymph nodes from untreated mice nor from mice injected with bone marrow and lymph nodes cells from isogenic donors: F_1 injected with F_1 cells, *C57Bl6* injected with *C57Bl6* cells.

Within the limits of our experiments, it can be asserted that this particular band shows only when: (*a*) there is a transplantation immunological reaction which in this particular case was a reaction of the grafted cells against the antigens of the host that the grafted cells did not possess; (*b*) when the number of hyperbasophilic cytoplasm cells is very high.

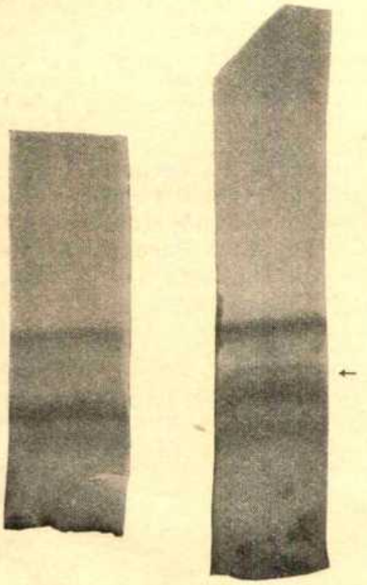

Fig. 1

Only the cathodic fraction of the gel is represented on the figure

It is not unreasonable to assume that the band shown in starch gel whenever an immunity reaction takes place in the lymph nodes together with the striking increase in number of hyperbasophilic cytoplasma cells might correspond indeed to the production of the antibody.

Lysine Synthesis and Phylogeny of Lower Fungi: Some Chytrids versus *Hyphochytrium*

RECENT work, conducted with the aid of various diagnostic carbon-14 tracers, has suggested that lysine biosynthesis is a valuable character in the detection of certain evolutionary relationships[1–4]. All the eubacteria, pseudomonads, actinomycetes[1], green algæ[2], and higher (vascular) plants[3] examined appear to synthesize lysine in one general manner (presumably via α,ε-diaminopimelic acid, cf. ref. 5) and all the ascomycetous and basidiomycetous fungi[1,3] (and also *Euglena*[2]) in another (presumably via α-aminoadipic acid, cf. ref. 6). Among the lower fungi (phycomycetes), a striking dichotomous distribution of the two lysine paths was noted: the Mucorales and Blastocladiales studied, like the higher fungi, evidently use the path via α-aminoadipic acid, and the Saprolegniales that via α,ε-diaminopimelic acid[4]. The present communication reports findings with some other phycomycetes, including three chytrids and a representative of the Hyphochytriales. The latter group of organisms, although closely paralleling the chytrids in body structure, have uncertain phylogenetic affinities.

The formation of lysine in the phycomycetes selected was investigated with the aid of radioactive DL-aspartate, DL-alanine, and acetate. Table 1

Table 1. INCORPORATION OF TRACERS INTO PROTEIN AMINO-ACIDS OF *Rhizophlyctis rosea* AND *Hyphochytrium catenoides* (AS SPECIFIC ACTIVITY RELATIVE TO THE RESPECTIVE PROTEIN ASPARTIC ACID VALUES)

Organism	Tracer	Aspartic acid	Threonine	Lysine
R. rosea	[4-^{14}C] Aspartate	100	104	< 5
R. rosea	[1-^{14}C] Alanine	100	95	< 5
R. rosea	[2-^{14}C] Acetate	100	91	440
H. catenoides	[4-^{14}C] Aspartate	100	94	107
H. catenoides	[1-^{14}C] Alanine	100	91	134
H. catenoides	[2-^{14}C] Acetate	100	90	90

The organisms were cultivated in 20 ml. of glucose-salts medium in 250-ml. flasks at 28° C., *R. rosea*, without shaking, in the medium of Stanier (ref. 7) and *H. catenoides*, with shaking, in that of Fuller (personal communication). Approximately 2–5 mgm. (20–50 μc.) of tracer were supplied per flask. For the determination of relative molar amounts of the three protein amino-acids, experiments with uniformly labelled glucose were performed. The cultures obtained were subjected to the collecting, extraction, hydrolysis, paper chromatography, and counting procedures previously described, and specific radioactivities of the protein amino-acids were computed on a molar basis, as before (refs. 3 and 8).

shows the labelling pattern found for the chytrid, *Rhizophlyctis rosea*, strain *QM*, obtained through the courtesy of Dr. J. N. Couch, and for a strain of *Hyphochytrium catenoides*, isolated by Dr. Couch and kindly furnished by Dr. M. S. Fuller. In the case of the former organism, the 4-carbon of aspartate and the 1-carbon of alanine are not appreciably incorporated into protein lysine, whereas the 2-carbon of acetate labels lysine heavily (in comparison with the labelling of protein aspartic acid and threonine). Essentially the same behaviour was shown by two other chytrids (generously provided by Dr. Couch and Dr. Fuller, respectively): *Phlyctochytrium punctatum*, strain *NG*-3 (ref. 9) and an organism similar to strain *QM*. In the case of *H. catenoides*, the 4-carbon of aspartate and the 2-carbon of acetate make approximately equal relative contributions to protein lysine, aspartic acid, and threonine; the 1-carbon of alanine contributes somewhat more extensively to lysine than can be accounted for by the conversion of the alanine to aspartic acid. In experiments with DL-[3-^{14}C] aspartate, the chytrids as well as *H. catenoides* showed substantial incorporation of carbon-14 into lysine. With regard to these labelling patterns, which will be discussed in more detail elsewhere, the chytrids are like the Blastocladiales, Mucorales, and higher fungi (as well as *Euglena*) and presumably have the α-aminoadipic acid–lysine path, whereas *H. catenoides* resembles the Saprolegniales and green algæ (as well as bacteria and vascular plants) and appears to use the α,ε-diaminopimelic acid–lysine path. It is noteworthy that the path via α-aminoadipic acid has thus far been indicated exclusively in those phycomycetes producing posteriorly uniflagellate zoospores or aplanospores, and the path via α,ε-diaminopimelic acid in those producing biflagellate or anteriorly uniflagellate zoospores.

The present results strengthen the view that the mode of lysine synthesis is a useful character in the exploration of certain phylogenetic links. The utility of this character is thought to depend in part on the fact that each of the two pathways contains a number of enzymes that appear to be specifically concerned with the formation of lysine. The two sets of enzymes are thus presumed to represent a considerable period of evolution and are viewed as biochemical organelles of ancient origin.

Grateful acknowledgement is made of the generous helpfulness of Dr. J. N. Couch and Dr. M. S. Fuller. Excellent technical assistance was provided by Mrs. Helen Carnevale. This work was aided by the National Science Foundation and by the Office of Naval Research.

Growth of Embryonic Mammalian Cartilage after Freezing

SINCE the discovery that glycerol will protect cells and tissues against freezing damage[1], considerable progress has been made in developing techniques for the preservation of tissues at very low temperatures. Attempts to establish low-temperature banks of adult human cartilage have unfortunately, so far, proved unsuccessful[2]. Biggers[3], however, was able to show that embryonic chick tibiæ will grow and differentiate *in vitro*, after freezing to −79° C., in saline containing 15 per cent glycerol. This communication describes briefly some of the work concerned with freezing embryonic rat tibiæ to −79° C. A fuller account is being given elsewhere[4]. Rat fœtuses of a known age were obtained from the Medical Research Council strain of albino rat, bred in the Department. The occurrence of a vaginal copulation plug, or the presence of sperm in the vaginal smear, was taken as the indication of mating. On the seventeenth day *post coitum*, the conceptuses were excised, and the embryonic tibiæ were isolated under a dissecting microscope. The bones were cleaned of as much extraneous tissue as possible, with care to avoid injuring the perichondrium. The structure of these tibiæ is being described elsewhere[5].

The embryonic bones were cultivated *in vitro* using either the plasma clot technique[6] or the floating-lens paper method[7]. The cooling technique employed was that described by Smith[8], and in all cases the frozen bones were thawed rapidly.

A preliminary series of experiments investigated the growth of 17-day embryonic rat bones after they had been equilibrated for various lengths of time in saline or plasma containing 15 per cent glycerol and then either frozen or explanted without freezing. Both the frozen and the unfrozen bones were rapidly rinsed in Tyrode's solution to remove any residual glycerol before they were explanted. In all these experiments, the frozen bones showed no subsequent elongation *in vitro*. Of the unfrozen bones, those which had been exposed to a concentration of 15 per cent glycerol, for periods not exceeding 30 min., elongated in a normal manner; those unfrozen bones that had been exposed to higher concentrations of glycerol-plasma, or for extended equilibration periods, did not afterwards elongate.

It was then decided to use trypsin, in an attempt to discover whether chondrocytes which were partially freed from their matrix would survive freezing. Tibiæ and femora from 17-day-old embryonic rat tibiæ were chopped into two or three pieces and digested with trypsin, using the method of Moscona and Moscona[9]. Tryptic digestion was carried out until the matrix was viscous and jelly-like, but the cells were still embedded in the matrix. The trypsin-treated cartilage was then suspended in 15 per cent glycerol plasma, and equilibrated for 30 min. at room temperature. Two thirds of the fragments were then cooled slowly to −79° C. and kept at this temperature for 1 hr. The remaining unfrozen fragments were briefly rinsed in Tyrode's solution to remove any residual glycerol and explanted. The frozen fragments were thawed rapidly, rinsed in Tyrode's solution, and explanted. Each culture contained fragments from approximately two bones. The explants were cultivated for five days and were sub-cultured after three days *in vitro*. Cartilage which survived the experimental treatments appeared healthy and viable; the amorphous fragments rounded up into whitish opaque nodules, regaining a definite shape after approximately 12 hr. *in vitro*. The nodules increased in size during the cultivation period, and, in addition, there was a peripheral outgrowth of clearly visible fibroblasts, growing in a radial pattern.

A similar experiment was carried out with cartilage from 18-day rat embryos. The tibiæ and femora were fragmented and treated in exactly the same way as described previously. As there appeared to be no difference between the survival of 17- and 18-day embryonic cartilage, or between tibiæ and femora, the results were combined and are shown in Table 1.

Table 1. RESULTS OBTAINED AFTER SLOWLY FREEZING EMBRYONIC RAT CARTILAGE FROM 17-DAY AND 18-DAY TIBIÆ AND FEMORA TO – 79° C. THE CARTILAGE WAS PRETREATED WITH TRYPSIN AND SUSPENDED IN 15 PER CENT GLYCEROL-PLASMA

	Killed	Survived	Total
Frozen	4	10	14
Unfrozen	1	9	10
Total	5	19	24

The probability of these results, or more extreme ones, arising from chance, was calculated using Fisher's exact method[10]. The probability was found to be $P = 0{\cdot}566$; thus, although there is a suggestion that the frozen cultures had a greater mortality than the non-frozen cultures, on the data obtained, this is nowhere near significant at the conventional $P = 0{\cdot}05$ level.

Histological examination of the explants which survived the experimental treatments revealed that both the rounded epiphyseal and the hypertrophic diaphyseal cells survived the freezing. The morphology of the cells was normal ; and when the sections were stained with toluidine blue, the characteristic metachromasia of the matrix was seen.

Temperature Coefficient of Endodiurnal Leaf Movements in *Phaseolus*

THE effect of temperature on the length of cycle of endodiurnal rhythms has been investigated in various processes in plants and animals. It was repeatedly found that within the physiological range the length of cycle is independent of temperature[1-3]. Several other endodiurnal rhythms, however, showed various temperature coefficients between 0·8 and > 3 (refs. 4–6). Went[7,8] reported a temperature coefficient in leaf movements of *Phaseolus* of 1·2 which is in agreement with early observations of Bünning[9]. Went, however, does not state under what conditions his plants were grown before measuring the cycle. As I have pointed out[10], the external conditions under which the seedlings are grown will determine the response. Etiolated plants, grown at 15, 20 and 25° C., showed a constant cycle-length of 28·0–28·3 hr. When the plants were grown in the greenhouse and then transferred to constant conditions, a Q_{10} of 1·2 was observed for the first two cycles ; the Q_{10} changed in the subsequent cycles to 0·9, thus revealing a temperature-compensating mechanism.

Went's statement[7] that my investigations "did not give any temperature effects on the cycle length but showed a constant 24-hr. cycle over a whole range of temperatures" is erroneous. I did not report a 24-hr. cycle in leaf movements. Went implies that a 24-hr. cycle of smoke and fog governed the leaf movements in my investigations. This assumption cannot be maintained since a cycle-length of 28 hr. was observed in etiolated plants. Furthermore, greenhouse-grown plants, measured at 20° C. at constant darkness, showed over five days a constant cycle-length of 26·1–26·7 hr. This finding by Lörcher[11], who used the same facilities as mine, does not reveal effects of external factors operating in regulating the *Phaseolus* clock.

Increased variability in the cycle-length under constant conditions[10] also indicates that the leaf movements were not controlled by external factors.

I showed that greenhouse-grown plants exhibit after transfer to constant conditions in the first two cycles after the transfer a Q_{10} of 1·2 the same coefficient as found by Bünning and Went. Whether or not the length of cycle is altered by temperature, however, is largely dependent on the pretreatment of the seedlings.

The Northern Rockling in the Clyde Sea Area

ON August 15, 1960, a northern rockling, *Ciliata septentrionalis* (Collett 1875), was caught in the Clyde Sea area. The fish was caught at a depth of 30–40 fathoms in a small mesh cover that had been fitted over the cod end of a trawl used by R.V. *Calanus*. It is 10·6 cm. in length and agrees closely with the descriptions of Smitt[1] and Schnackenback[2].

This is the first record of *Ciliata septentrionalis* from Britain. Elsewhere it has been recorded in Norway between 70° 13′ N. and Bergen[3] and from south Greenland[4]. I have previously found two specimens in a jar in the Sales Department here, but there was no record of when the fish were preserved, who preserved them or where they came from. However, it now seems probable that the fish lives permanently in the Clyde.

BACTERIOLOGY

Variation of Elasticity along Single Microfibrils of Bacterial Cellulose

A NUMBER of models have been proposed for the internal fine structure of individual cellulose microfibrils which suggest variability both across and along the axis of the microfibril. Frey-Wyssling[1] has suggested that microfibrils are subdivided into four continuous crystalline strands, each about 70 Å. wide, which run parallel to the microfibril axis and are held together by a paracrystalline matrix. In contrast, Preston[2] has concluded that cellulose microfibrils from algæ are composed of a paracrystalline sheath surrounding a highly crystalline single core which is interrupted at random positions by less-crystalline material labile to electron bombardment. The positions occupied by this material may coincide with the sites of trace residues (*Fremdgruppen*) postulated by H. K. Meyer and van der Wyk and by Treiber[3].

In this contribution is presented direct evidence for random variation of elasticity along the length of individual microfibrils of bacterial cellulose.

Cellulose-free, washed cells of *Acetobacter xylinum* were prepared as described previously[4], and 1 ml. of the suspension used to inoculate 35 ml. of sterile medium[5] in Petri dishes, 10-cm. in diameter. Sterile microscope slides were slipped beneath the surface of the medium, and on top of the slides were placed several sterile copper electron microscope grids. Each culture was incubated in covered Petri dishes 4–12 hr. at 30° C. The glass slides carrying the electron microscope grids were gently lifted from the medium (horizontally) and air dried. The dried slides were washed in a slow current of water with a minimum of agitation. The grids with adherent microfibrils were again dried, shadowed with palladium–gold (60 : 40) at an angle of 15° to increase electron scattering and examined.

Examination at low beam intensities showed single straight microfibrils or straight bundles of microfibrils extending over distances of more than 70μ without support. As beam intensity was increased, the single microfibrils or bundles began to coil into rough irregular helices (Fig. 1), presumably because of differential heating of the shadowed and unshadowed halves of the microfibrils. The degree of coiling depended on the maximum intensity to which the microfibrils were exposed and was irreversible.

No appreciable relaxation of the microfibrils to their original straight form was observed on reduction of beam intensity, but an extension or contraction of the coil on variation of beam intensity was often seen. That the coiled microfibrils were under severe longitudinal strain was shown by frequent snapping and sharp recoil of the threads to form tangled clumps (Fig. 1). The twisting of individual microfibrils exhibited their flattish ribbon-like outline clearly (Fig. 2).

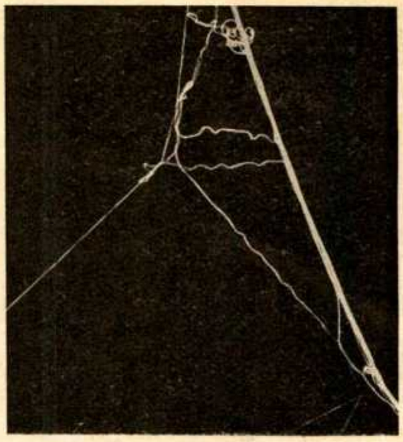

Fig. 1. Helices of bacterial cellulose microfibrils formed by heating shadowed straight microfibrils or bundles in an electron beam. Note tangled clump of microfibrils, formed after breaking in the electron beam

The most interesting property shown by the above helices was the marked variation in coiling of the same microfibril or bundle of microfibrils from point to point along its length (Fig. 3). Not all microfibrils, were coiled, perhaps because of the extreme tension to which some were subjected, but of those which did the pitch of the helix often changed abruptly. Since the total stress was the same at any point of an unsupported segment of a single microfibril, this variation in pitch must reflect a corresponding variation of elasticity at different portions of the thread. Similarly, in a bundle of microfibrils, variation of the pitch of the helix of the bundle must reflect a variation of the composite bundle modulus, which in turn implies variations of the modulus in single microfibrils. Since the angle and degree of metal shadowing, as well as the electron-beam intensity, were uniform along any initially straight microfibril, the above variation in elasticity may be attributed to either a corresponding variation in twisting of the

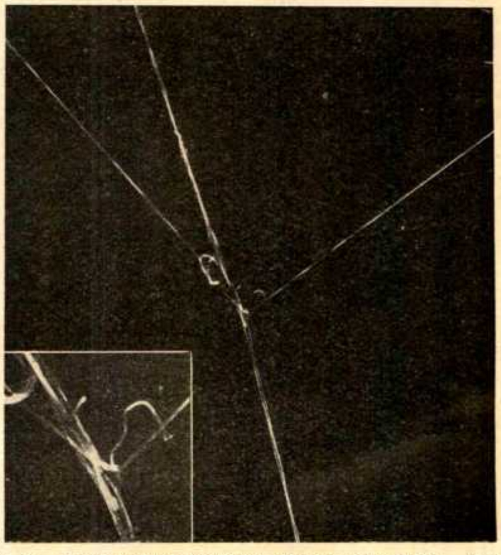

Fig. 2. Single twisted bacterial cellulose microfibrils. Inset: Note end of broken microfibril which may be frayed

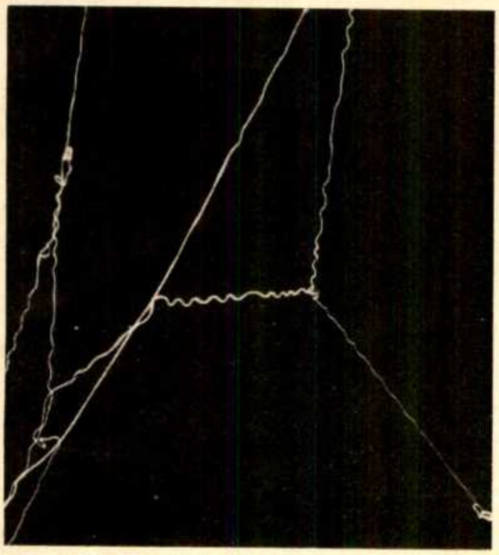

Fig. 3. Helical microfibrils showing the abrupt variation in pitch along their length

original microfibrils or to variations in the fine structure of straight ones. However, if the original microfibrils are irregularly twisted, this also implies a linear variation of internal fine structure. Thus either attribution points to a variation of fine structure along single microfibrils. This variation may be due to differences in crystallinity along the microfibril, differences in the number of β-glucosan chains composing the microfibril at various points, variations in the type of packing of glucose residues within the unit cell or variations in the local content of trace residues along the microfibril.

The random variation of tensile strength along microfibrils of bacterial cellulose suggests that their fine structure is closer to the model proposed by Preston for *Valonia* cellulose than that suggested by Frey-Wyssling, since variations along four crystalline continuous sub-filaments would tend to cancel out. Also, if sub-filaments existed in single microfibrils of bacterial cellulose, fraying on breakage should be evident; but only one tentative instance out of several hundred was noted (Fig. 2). This single observation may also be attributed to irregular fracture along a solid core and is therefore not conclusive.

Since bacterial cellulose microfibrils grow at the tips[4,6], the observed variation in tensile properties implies corresponding deviations in the detailed mechanism of deposition and crystallization of individual glucose residues during fibrogenesis. Such deviations, however, must be only digressions from a stable process since clearly they are corrected quickly. The inference of such temporary deviations is also supported by Ränby's recent observation that bacterial cellulose microfibrils which have never been dried have approximately 25 per cent more accessibility to tritium atoms than the same material after drying[7].

GENETICS

Genetic Recombination in *Vibrio cholerae*

THE occurrence of genetic recombination in *V. cholerae*, revealed by crosses between double auxotrophic mutants of strain 162, was mediated by a fertility factor—designated the *P* factor—which could be infectively transmitted from strain to strain by conjugation[1]. P^+ strains (possessing the fertility factor) gave rise to recombinants when crossed with P^- strains (devoid of the fertility factor).

The relative roles of P^+ and P^- strains in such crosses have now been elucidated. When P^+ strains, suspended in minimal medium, were exposed to ultra-violet light to reduce their viable count by a factor of 1/1,000 to 1/10,000 and then crossed with normal P^- strains there was a considerable stimulation of recombination as judged by the number of colonies which appeared on selective media. If, on the other hand, P^- strains were likewise exposed to ultra-violet light to effect a similar reduction in viable count and then crossed with normal P^+ culture, recombination was almost completely abolished. This differential effect of ultra-violet light has been confirmed in four different crosses between P^+ and P^- mutant stocks. Table 1 furnishes details of one such cross. P^- strains grown in broth culture supernatants of

Table 1. EFFECT OF ULTRA-VIOLET IRRADIATION OF PARENT STRAINS ON GENETIC RECOMBINATION IN *Vibrio cholerae* CROSS $V44P^+$(*pur*, *arg*, *str-r*, 200-*r*) × $V39P^-$ (*ilva*, *str-s*, 200-*s*)

$V44P^+$(U.V.) × $V39P^-$ (U.V.)	$1\cdot0 \times 10^4 + 2\cdot3 \times 10^4$ $3\cdot0 \times 10^3 + 8\cdot0 \times 10^3$	3 nil	4 nil	nil nil	nil nil

U.V., irradiated with ultra-violet light; 200-*s*, sensitivity to phage 200; 200-*r*, resistance to phage 200; *pur*, *arg*, requirement for purine and arginine; *ilva*, requirement for valine and *iso*leucine; *str-s*, sensitivity to streptomycin; *str-r*, resistance to streptomycin.

irradiated P^+ cultures did not give rise to recombinants.

The differential lethal effect of ultra-violet light on P^+ and P^- strains shows that recombinants arise from the P^- parent, which probably functions as a gene-acceptor. P^+ strain appears to be a gene-donor, the viability of which is not essential for the expression of the recombinants.

A similar situation is now well recognized in *Escherichia coli*[2,3] in which it was first demonstrated by the differential effect of streptomycin[4] on F^+ and F^- strains. The streptomycin method was not suitable for *V. cholerae*, as it resulted in a marked reduction in recombination-rate. Nevertheless, a significant number of recombinants could be obtained when P^+ strains were treated with streptomycin and crossed with P^- cultures and none at all if P^- strains were treated with streptomycin and crossed with P^+ cultures. Full details of this work will be published elsewhere.

Histocompatible Colour Mutant from *CBA/Lab* Strain of Mice

The progeny from a breeding pair of *CBA/Lab* mice, a strain which is propagated by brother × sister mating, were found to have grey agouti coats in contrast to the usual wild-type agouti of the strain. These '*CBA* grey' mice when mated together produced similar 'grey' mice among their progeny (that is, the 'grey' character behaved as if it were determined by a recessive gene), and it was thought to be of interest to test the original strain and its mutant for histocompatibility.

The results are shown in the photographs of skin grafts from normal *CBA* and mutant animals on a *CBA* mouse (Fig. 1) and on a mutant *CBA* mouse (Fig. 2) indicate histocompatibility between the two lines. A similar compatibility to skin grafting between a *CBA* mutant *p* (pink eye) and its host was found by Fraser and Clayton[1]. In a later communication given in the Institute of Animal Genetics Research Report 1955–1957, Mrs. Clayton refers to antigenic differences between these two types.

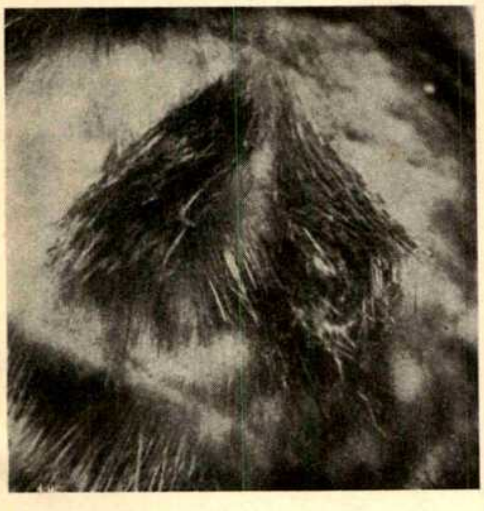

Fig. 1

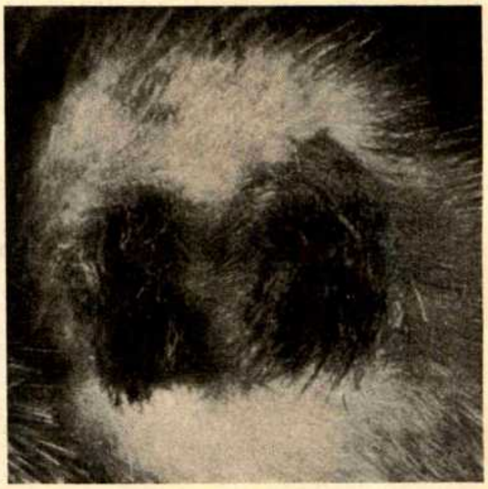

Fig. 2

Preliminary tests by Dr. Mary Lyon of the Radiobiological Research Unit, Harwell, to determine the gene that our mutant carries have shown that grey is not the same as or allelic with genes *a*, *b*, c^{ch}, *d*, *pa* or *p* (pink eye). This does not necessarily mean that it is a new mutant, and further tests are progressing

PSYCHOLOGY

Theory of the Visual Threshold

Gregory[1] and Cane and Gregory[2] have put forward a theoretical equation for the brightness increment threshold considered as a statistical discrimination. For a given frequency of detection they propose that:

$$\frac{[(r + \Delta r) - r] - C}{\sqrt{\left(\frac{1}{A_1} + \frac{1}{A_2}\right) V}} = \text{const.} \qquad (1)$$

where $(r + \Delta r)$, r, are the mean neural pulse-rates associated with the intensities $(I + \Delta I)$, I, and V is the variance of these rates. C is a constant necessary to account for the occurrence of fewer than 50 per cent false positives. Its implication, as stated by Gregory, is that "some fixed difference between impulse rates is required before discrimination is established, this difference being independent of the intensity I".

This equation can be regarded as an adaptation of Thurstone's[3] law of comparative judgment, case 3, for answers of 'yes' or 'no' in place of comparisons. The term:

$$\sqrt{\left(\frac{1}{A_1} + \frac{1}{A_2}\right) V}$$

can be regarded as the standard deviation of the distribution of $[(r + \Delta r) - r]$, assuming the two terms to be uncorrelated, and will be further referred to as σ_r. The constant will be called b.

Marriott[4] has shown that this equation leads to rather implausible consequences: (1) Although when the threshold is defined by a criterion such as 80 per cent of positive responses, ΔI will decrease as the area increases (causing σ_r to decrease), as Gregory[1] found, this will not be true when the criterion is 50 per cent positive responses, in which case threshold will be independent of changes in area. (2) With a criterion such as 20 per cent, ΔI decreases as the area decreases (σ_r increases). It might be added (3) that though the threshold will stay constant despite changes in area with a 50 per cent criterion, the false positive rate will decrease as the area increases. Consequently, Marriott rejects the approximations to Ricco's and Piper's laws for areal summation at the absolute threshold which Cane and Gregory derive from their assumptions.

The modification of the equation in a way suggested by the theory of signal detectability appears capable of avoiding these difficulties. In place of Gregory's assumption that a fixed difference between impulse-rates (or whatever central effects of the stimuli determine the responses) is required by the brain to establish discrimination, let us suppose that the discrimination mechanism operates to give maximum detection consistent with a limiting rate of false positive responses. In this case the value of C will not be constant, but must be defined as a function of σ_r. Let us therefore replace it by $m\sigma_r$, where the value of m determines the proportion of false positives. Thus, when $m = 2$, the false positive rate would be approximately equal to 2·5 per cent. The equation for the threshold can now be expressed as:

$$[(r + \Delta r) - r] = (m + b)\sigma_r \qquad (2)$$

Assuming that the distribution of $[(r + \Delta r) - r]$ is approximately normal, b is the normal deviate corresponding to the frequency of response required to define the threshold. When this is 50 per cent, $b = 0$ and the right-hand terms reduce to $m\sigma_r$. Thus the threshold is still directly proportional to σ_r, so that it will vary with area just as when it is defined by an 80 per cent requirement. This meets Marriott's first point. When the requirement is 20 per cent, the equation becomes $(r + \Delta r) - r = (m - b)\sigma_r$, where b is the normal deviate corresponding to 80 per cent negative responses. In this case too the threshold will decrease as σ_r decreases, that is, as the area increases, thus meeting the second objection. Moreover, so long as the response-rate required to define the threshold exceeds the false positive rate, $(m - b)$ will be positive.

Even though the threshold equation in the form above meets Marriott's objections, there is still reason to doubt the derivation of Ricco's and Piper's laws, based on the assumption that r is proportional to $\log(I + k)$, which is offered by Cane and Gregory, where k is a constant assumed by Gregory to represent the internal noise of the system. A very similar result is given by equation (2) to that obtained by Cane and Gregory with equation (1). At the absolute threshold, where $I = 0$, taking exponents in equation (2), and ignoring A_2, which is the total visual field, we get:

$$1 + \frac{\Delta I}{k} = e^{(m+b)V^{1/2}A^{-1/2}} \qquad (3)$$

Defining the unit of I so that $k = 1$, and putting $(m + b)V^{\frac{1}{2}} = d$, we get for the absolute threshold:

$$\Delta I = d/A^{1/2} + d^2/2A + d^3/6A^{3/2} \ldots \qquad (4)$$

Cane and Gregory obtain Ricco's law by multiplying throughout by A, and Piper's law by multiplying by $A^{1/2}$. In each case a constant appears among the terms on the right. However, it has been pointed out to me by Dr. Marriott (private communication) that in the first case it is the second term (as given in equation (4)) which provides the constant and in the second case the first term. This causes the following difficulty: the values of the terms on the right depend on the values of both d and A. While d and A can have values such that the first term is considerably larger than any other term, and decrease in the value of A will increase the size of the second term relative to the first term, it will cause the values of other terms to increase as well, and at no time will the second term be more than a fraction of the total value of ΔI (for example, if $d = 1$, $A = 10$, the first terms are 0·3, 0·05, 0·005. . . . If A is made 0·1, the terms are 3·2, 5·0, 5·3 . . .). Thus the unmodified assumption of a simple logarithmic transformation of the stimulus, so far from leading to Ricco's law, appears to exclude it.

I wish to thank Prof. R. C. Oldfield for research facilities, and Dr. C. I. Howarth and Dr. F. H. C. Marriott for helpful discussions.

SOCIOLOGY

Conflicting Hypotheses on the Growth of World Population

Over the past twenty thousand years, the logarithm of human population of small areas such as England and Wales—when plotted against time—shows two or more special upsurges, or kinks; for example, due to the introduction of agriculture, or since A.D. 1500. One may recognize three main demographic stages[1]. With the same idea, Prof. E. S. Deevey of Yale proposes a striking plot of total world population, featuring two such kinks in a very pronounced manner[2]. But the "overall geographical speed of cultural diffusion", in early times, was slow: often between 0·5 and 5 km. per annum[3]. Consequently different small areas had their main kinks at widely different times; and they will practically disappear on summation. Hence, with due allowance for the different scales used, the relatively smooth curve for world population[4] seems likely to be much nearer the truth than Deevey's of the following September.

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Monday, March 27

British Institution of Radio Engineers, Medical Electronics Group (at the Postgraduate Medical School, University of London, Hammersmith, London, W.12), at 3 p.m.—Symposium on "Electronic Instrumentation for Cardiac Surgery".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. G. de Q. Robin : "The Antarctic Ice Sheet".

Institution of Mechanical Engineers, Internal Combustion Engines Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Is Fuel-Injection Equipment Standardization Limiting the Development of Small Diesel Engines?".

Operational Research Society (in the Lecture Theatre of the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Mr. D. T. Steer : "Feasibility and Financial Studies of a Port Installation".

Monday, March 27—Wednesday, March 29

Biochemical Society (in London)—Fiftieth Anniversary Meeting.

Monday, March 27—Tuesday, March 28

(In the Senate House, University of London, W.C.1)—Symposium on "Structure and Synthesis of Macromolecules".

Tuesday, March 28

(At the Royal Institution, Albemarle Street, London, W.1)—Sir Hans Krebs : "The Physiological Role of Ketone Bodies" (Third Hopkins Memorial Lecture).

Wednesday, March 29

(At University College, Gower Street, London, W.C.1)—Original Communications and Annual General Meeting.

Tuesday, March 28

Society of Instrument Technology, Control Section (at 26 Portland Place, London, W.1), at 5 p.m.—Dr. P. E. W. Grensted and Mr. O. L. R. Jacobs : "Automatic Optimization". 7 p.m.—Mr. P. F. Sutherby : "The Development of an Optimizing Controller".

Royal Society of Medicine, Medicine Section (at 1 Wimpole Street, London, W.1), at 8 p.m.—Meeting on "Isotopes in Medicine" Speakers : Prof. G. M. Wilson, Prof. D. W. Smithers and Dr. E. Williams.

Tuesday, March 28—Thursday, March 30

Royal Institution of Naval Architects (in the Weir Lecture Hall, 10 Upper Belgrave Street, London, S.W.1), at 10.15 a.m. daily —Spring Meeting.

Wednesday, March 29

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 3 p.m.—Symposium on "Electronic Instrumentation for Nuclear Power Stations".

Institution of Mechanical Engineers (in conjunction with the Steam Plant Group, at 1 Birdcage Walk, Westminster, London, S.W.1), at 3.30 p.m.—Mr. R. W. Haywood, Mr. C. A. Knights, Mr. C. E. Middleton and Mr. J. R. S. Thom: "An Experimental Study of the Flow Conditions and Pressure Drop of Steam-Water Mixtures at High Pressures in Heated and Unheated Tubes".

Society for Analytical Chemistry (at the Chelsea College of Technology, Manresa Road, Chelsea, London, S.W.3), at 6 p.m.—Demonstration of Laboratory-Made Equipment".

Royal Aeronautical Society, Agricultural Aviation Group (at 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. R. P. Fraser : "Atomization".

Royal Institute of Chemistry (at Hendon Technical College, The Burroughs, London, N.W.4), at 7.30 p.m.—Dr. K. G. A. Pankhurst: "The Story of Soap and the Growth of Modern Synthetic Detergents".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned :

Senior Research Assistant (postdoctoral standard, qualified in inorganic chemistry), to take part in an investigation of the crystal chemistry of oxides and hydroxides of the transition metals—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (April 5).

Research Fellow (with a first degree in biochemistry, chemistry or botany, and research experience in biochemistry and particularly in the use of radioactive tracers) in Plant Biochemistry in the Department of Botany, to participate in research on the mechanism of photosynthesis—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (April 7).

Lecturer or Assistant Lecturer in Zoology—The Secretary, The University, Exeter (April 10).

Zoology Assistant (Grade B) (with good academic qualifications) in the Department of Botany and Zoology—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (April 10).

Assistant in Physical or Inorganic Chemistry—Joint Clerk to the University Court, Queen's College (University of St. Andrews), Dundee (April 15).

Chair of Agriculture; Chair of Physics; Chair of Education; and Chair of Geography—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas (Dept. T.1), 29 Woburn Square, London, W.C.1 (April 15).

Lecturer in Microbiology; and a Lecturer or Assistant Lecturer in Pharmacology at the University College of the West Indies—The Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W.C.1 (April 17).

Chair of Zoology tenable in the Durham Division of the University —The Registrar, University Office, 40 North Bailey, Durham (April 22).

Organic Chemist (graduate, or holder of a technical college diploma majoring in organic chemistry, and preferably with experience of distillation and chromatographic techniques) in the Division of Coal Research, C.S.I.R.O., Sydney, Australia, to assist on investigations of the chemical constitution of coal tar and pitch and in the development of new industrial uses for these materials—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 480/359 (April 22).

Imperial Chemical Industries Research Fellows in Biochemistry, Chemistry, Chemotherapy, Engineering, Metallurgy, Pharmacology or Physics—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 25).

Lecturer in Mathematics at the University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 25).

Senior Lecturer in Physics; a Senior Lecturer (graduate with Corporate Membership of the Institution of Electrical Engineers) in Electrical Engineering; a Lecturer in Botany; a Lecturer or Assistant Lecturer (preferably with qualifications in physical and/or inorganic chemistry) in Chemistry; and a Lecturer (preferably with qualifications and/or experience in palæontology, stratigraphy or structural physical geology) in Geology, at the Royal College, Nairobi—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 25).

Assistant Lecturer (honours graduate) in Physiology; and an Assistant Lecturer (honours graduate) in Biochemistry—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (April 28).

Lecturer in Philosophy at the University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, April 28).

Senior Lecturer/Lecturer (preferably with previous research experience) in the Department of Statistics of the School of Mathematics, University of New South Wales, Kensington—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2 (Australia and London, April 30).

Burn Research Fellow (graduate, not less than thirty years old, with two or three years research experience) in Pharmacology at Oxford—Secretary to the Trustees, Department of Pharmacology, University of Oxford (May 15).

Lecturer or Senior Lecturer in Mathematics at the University of Tasmania, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, May 15).

Chair of Agriculture in the University of Tasmania, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, May 31).

McCaughey Chair of Geography in the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, May 31).

Assistant Lecturer (preferably with research experience in some field of experimental zoology) in the Department of Biology as Applied to Medicine—The Secretary, Department of Biology as Applied to Medicine, Middlesex Hospital Medical School, London, W.1 (July 1).

Lecturer and an Assistant Lecturer in the Department of Anatomy—The Secretary, University College London, Gower Street, London, W.C.1.

Master to teach Mathematics to G.C.E. "O" level—The Headmaster, Queen Elizabeth's Grammar School, Blackburn.

Reader, and a Lecturer, in Low Temperature Physics—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11.

Research Assistants (with a degree in chemistry or chemical engineering, or with equivalent qualifications such as Grad.R.I.C.) in the Department of Chemistry, for experimental work on the thermodynamic properties of gases and of liquid mixtures—The Bursar, The University, Reading.

Research Chemist (with experience of research work in physical chemistry or chemical engineering, and preferably with a higher degree in one of these subjects) in the Department of Chemistry to continue a study of the thermodynamics of imperfect gases, under the items of a contract between the University and the D.S.I.R.—The Registrar (Room 22 O.R.B.), The University, Reading.

Research Consultant (with sound British academic qualifications, and specialized in physical or inorganic chemistry) in the Centre of Chemistry at the University of Chile, Santiago, to conduct and advise on research, advise on the organization of the Centre, and to conduct courses for the research staff—The Director, Recruitment Department, The British Council, 65 Davies Street, London, W.1, quoting Ref. N.4.T(61).

Whole-time Biochemist (non-resident), for hospital biochemical work in the Mansfield Area Pathology Service—The Hospital Secretary, King's Mill Hospital, Sutton-in-Ashfield, Notts.
